ABSTRACT

With the release of the first-year *Fermi* catalogue, the number of blazars detected above 100 MeV lying at high redshift has been largely increased. There are 28 blazars at $z > 2$ in the ‘clean’ sample. All of them are flat spectrum radio quasars. We study and model their overall spectral energy distribution in order to find the physical parameters of the jet-emitting region, and for all of them, we estimate their black hole masses and accretion rates. We then compare the jet with the accretion disc properties, setting these sources in the broader context of all the other bright γ -ray or hard X-ray blazars. We confirm that the jet power correlates with the accretion luminosity. We find that the high-energy emission peak shifts to smaller frequencies as the observed luminosity increases, according to the blazar sequence, making the hard X-ray band the most suitable for searching the most-luminous and distant blazars.

Key words: radiation mechanisms: non-thermal – BL Lacertae objects: general – quasars: general – gamma-rays: general – X-rays: general.

1 INTRODUCTION

The Large Area Telescope (LAT) onboard the *Fermi* satellite detected, after 11 months of all-sky survey, more than 1400 sources, presented in Abdo et al. (2010a), with roughly half of them being BL Lac objects or flat spectrum radio quasars (FSRQs) (Abdo et al. 2010b, hereinafter A10), and a few radio galaxies, starburst galaxies and narrow-line type 1 Seyfert galaxies. The corresponding catalogue of active galactic nuclei (AGNs) at high Galactic latitude ($|b| > 10^\circ$) is called the First LAT AGN Catalog (1LAC). BL Lacs and FSRQs are approximately present in equal number.

With respect to the previous sample (LAT Bright AGN Sample, hereinafter LBAS), constructed after 3 months of survey (Abdo et al. 2009a; hereinafter A09), the number of detected blazars is about seven times larger, as a result of the lower limiting sensitivity, obtained with the longer exposure and the smaller required significance (from 10σ of the first 3 months to the current 4σ level). Correspondingly, the number of high-redshift blazars detected in γ -rays also increased: in the LBAS, there were five blazars at $z > 2$ (and none at $z > 3$), while in the 1LAC catalogue, there are 28 sources at $z > 2$ (and 2 at $z > 3$).

The increased number of high-redshift γ -ray blazars allows us to characterize them in a meaningful way, through their spectral energy distributions (SEDs) and their modelling. Indeed, the coverage at other frequencies (besides the *Fermi*/LAT band) includes observations by the *Swift* satellite for all sources both in the optical–ultraviolet (optical–UV) band [through the *Swift*’s Ultraviolet/Optical Telescope (UVOT)] and the soft X-ray band [0.3–10 keV, through the X-Ray Telescope (XRT)].

It is also interesting to compare the properties of the high-redshift blazars detected in γ -rays with the high-redshift blazars detected in hard X-rays by the Burst Alert Telescope (BAT) instrument onboard the *Swift* satellite. All blazars at $z > 2$ are FSRQs, so, up to now, high-redshift ‘blazars’ coincide with high-redshift FSRQs, since no BL Lac objects with a measured redshift $z > 2$ have been detected so far. There are 10 FSRQs at $z > 2$ and five at $z > 3$ in the 3-yr BAT all-sky survey presented by Ajello et al. (2009), which have been studied in Ghisellini et al. (2010a, hereinafter G10). The BAT and the LAT samples of high-redshift blazars are rather well defined, since the sky coverage is quasi-uniform (excluding the Galactic plane) and we can consider these samples as flux limited.

The main objectives of this paper are then to characterize the properties of blazars detected at high energies at redshifts greater than 2 and to see if we can understand the differences (if any) between the blazars detected in the two bands (γ -rays and hard X-rays). In G10, in fact, we suggested that the best way to select the

*E-mail: gabriele.ghisellini@brera.inaf.it

most powerful blazars at large redshifts is through a survey in the hard X-ray band, rather than in the γ -ray one, but this was based on small numbers. None of the 10 BAT blazars at $z > 2$ is present in the LBAS catalogue and only four of them are in the ILAC sample, that is, have been detected after 11 months of survey by the *Fermi*/LAT instrument. In G10, we explained this through a change in the average SED when the bolometric luminosity changes: by increasing it, the high-energy hump of the SED peaks at smaller frequencies, in agreement with the blazar sequence as put forward by Fossati et al. (1998) and Donato et al. (2001), and interpreted in Ghisellini et al. (1998).

We anticipate that our earlier suggestion remains valid, with important implications on the planned future hard X-ray survey missions, such as *EXIST*.

In this paper, we use a cosmology with $h = \Omega_{\Lambda} = 0.7$ and $\Omega_M = 0.3$, and use the notation $Q = 10^x Q_x$ in cgs units (except for the black hole masses measured in solar mass units).

2 THE HIGH-REDSHIFT SAMPLE

We consider all blazars detected during the first-year all-sky survey of *Fermi* and classified as ‘clean’ in the catalogue of A10. These are all the blazars with $|b| > 10^\circ$, detected at more than the 4σ level whose identification is secure and unique. In total, the ILAC clean sample contains 599 sources (A10), of which 248 are FSRQs, all with a measured redshift, and 275 BL Lacs (116 with the redshift measured). Among these, we selected the 27 blazars at $z > 2$ as listed and classified by A10, plus an additional source, SWIFT J1656.3–3302 ($z = 2.4$), that Ghirlanda et al. (2010) recently classified as an FSRQ among the unidentified ILAC sources.

Five of these were already present in the LBAS list, that is, the blazars detected at more than the 10σ level during the first 3 months of *Fermi* survey (A09). Four additional sources are present in the 3-yr survey of *Swift*/BAT (A09) and they too have been studied in G10.

Table 1 lists all sources: the top 19 blazars are studied in this paper, while the bottom nine blazars are the sources already present either in the BAT or in the LBASs. In this paper, we present the SED and the modelling for the ‘new’ ones, that is, blazars not present in our previous study (G10).

3 SWIFT OBSERVATIONS AND ANALYSIS

For all blazars studied in this paper, there are *Swift* observations. Even when they were performed during the 11 months of the ILAC survey, they correspond to a ‘snapshot’ of the optical–X-ray state of the source, while the γ -ray data are an average over the 11 months. Given the very rapid blazar variability, the SEDs constructed in this way should be considered, in all cases, not simultaneous (but the *Swift* UVOT and XRT data are indeed simultaneous).

The data were screened, cleaned and analysed with the software package HEASOFT v6.8, with the calibration data base updated to 2009 December 30. The XRT data were processed with the standard procedures (XRTPIPELINE v0.12.4). All sources were observed in the photon counting mode and grade 0–12 (single to quadruple pixel) was selected. The channels with energies below 0.2 keV and above 10 keV were excluded from the fit and the spectra were rebinned in energy so to have at least 20–30 counts per bin in order to apply the χ^2 test. When there are no sufficient counts, we applied the likelihood statistic in the form reported by Cash (1979). Each spectrum was analysed through XSPEC v12.5.1n with an absorbed power-law model with a fixed Galactic column density as measured

Table 1. List of blazars at $z > 2$. The upper part of the table reports the blazars studied in this paper (denoted by ‘0’ in the last column), while the bottom part reports blazars studied previously: in Ghisellini et al. (2010a; G10) (blazars with $z > 2$ detected by *Swift*/BAT); and in Ghisellini et al. (2009b, G09) (blazars with $z > 2$ in LBAS with $L_\gamma > 10^{48}$ erg s $^{-1}$).

by Kalberla et al. (2005). The computed errors represent the 90 per cent confidence interval on the spectral parameters. Table 2 reports the log of the observations and the best-fitting results of the X-ray data with a simple power-law model. The X-ray spectra displayed in the SED have been properly rebinned to ensure the best visualization.

UVOT (Roming et al. 2005) source counts were extracted from a circular region 5 arcsec in size – centred on the source position, while the background was extracted from a larger circular nearby source-free region. Data were integrated with the ‘uvotimsum’ task and then analysed by using the ‘uvotsource’ task. The observed magnitudes have been dereddened according to the formulae by Cardelli, Clayton & Mathis (1989) and converted into fluxes by using standard formulae and zero-points from Poole et al. (2008). Table 3 lists the observed magnitudes in the six filters of the UVOT.

4 MODELLING THE SPECTRAL ENERGY DISTRIBUTION

To model the SEDs of the blazars in this sample, we used the same model as used in G10. It is a one-zone, leptonic model, fully discussed in Ghisellini & Tavecchio (2009). In that paper, we emphasized the relative importance of the different sources of the seed photons for the inverse Compton scattering process and how they change as a function of the distance of the emitting region from the black hole. Here we briefly summarize the main characteristics of the model.

Table 2. Summary of XRT observations. The observation date column indicates the date of a single snapshot or the years during which multiple snapshots were performed. The corresponding note reports the complete set of observations integrated. The column ‘Exposure’ indicates the effective exposure in ks, while N_{H} is the Galactic absorption column in units of 10^{20} cm^{-2} from Kalberla et al. (2005). Γ is the photon index of the power-law model [$F(E) \propto E^{-\Gamma}$] and $F_{0.2-10\text{keV}}^{\text{obs}}$ is the observed (absorbed) flux. The last two columns indicate the results of the statistical analysis: the last column contains the degrees of freedom, while the last but one column displays the reduced χ^2 or the value of the likelihood (Cash 1979), in case there are no sufficient counts to apply the χ^2 test.

Name	Observation date (DD/MM/YYYY)	Exposure (ks)	N_{H} (10^{20} cm^{-2})	Γ	$F_{0.2-10\text{keV}}^{\text{obs}}$ ($10^{-13} \text{ erg cm}^{-2} \text{ s}^{-1}$)	χ^2/Cash	d.o.f.

The source is assumed spherical (radius R) and located at a distance R_{diss} from the central black hole. The emitting electrons are injected at a rate $Q(\gamma)$ ($\text{cm}^{-3} \text{s}^{-1}$) for a finite time equal to the light crossing time R/c . The shape of $Q(\gamma)$ we adopt is assumed to be a smoothly broken power law with a break at γ_b :

$$Q(\gamma) = Q_0 \frac{(\gamma/\gamma_b)^{-s_1}}{1 + (\gamma/\gamma_b)^{-s_1+s_2}}. \quad (1)$$

The emitting region is moving with a velocity βc corresponding to a bulk Lorentz factor Γ . We observe the source at the viewing angle θ_v and the Doppler factor is $\delta = 1/[\Gamma(1 - \beta \cos \theta_v)]$. The magnetic field B is tangled and uniform throughout the emitting region. We take into account several sources of radiation externally to the jet: (i) the broad-line photons assumed to re-emit 10 per cent of the accretion luminosity from a shell-like distribution of clouds located at a distance $R_{\text{BLR}} = 10^{17} L_{\text{d},45}^{1/2}$ cm; (ii) the infrared (IR) emission from a dusty torus, located at a distance $R_{\text{IR}} = 2.5 \times 10^{18} L_{\text{d},45}^{1/2}$ cm; and (iii) the direct emission from the accretion disc, including its X-ray corona. Furthermore, we take into account the starlight contribution from the inner region of the host galaxy and the cosmic background radiation, but these photon sources are unimportant in our case. All these contributions are evaluated in the blob comoving frame,

where we calculate the corresponding inverse Compton radiation from all these components and then transform into the observer frame.

We calculate the energy distribution $N(\gamma)$ (cm^{-3}) of the emitting particles at the particular time R/c , when the injection process ends. Our numerical code solves the continuity equation, which includes injection, radiative cooling and e^\pm pair production and reprocessing. Ours is not a time-dependent code: we give a ‘snapshot’ of the predicted SED at the time R/c , when the particle distribution $N(\gamma)$ and consequently the produced flux are at their maximum.

For all sources in our sample, the radiative cooling time of the particles is short, shorter than R/c even for low-energy particles. In Table 4 (last column), we have listed the values of γ_c , that is, the minimum value of the random Lorentz factor of electrons cooling in one light crossing time. Since it is always smaller than γ_b , almost all the energy injected in the form of relativistic electrons is radiated away. Most of the cooling is due to the inverse Compton scattering with broad-line photons, with a minor contribution from the synchrotron and the self-Compton process. Therefore, we always are in the *fast-cooling* regime (i.e. $\gamma_c < \gamma_b$). In this regime, the produced luminosity *does not depend* on the amount of the radiation energy density, but only on the energy content of the injected relativistic electrons.

Table 4. List of parameters used to construct the theoretical SED. Not all of them are ‘input parameters’ for the model, because R_{BLR} is uniquely determined from L_d , and the cooling energy γ_c is a derived parameter. Column [1]: name; Column [2]: redshift; Column [3]: dissipation radius in units of 10^{15} cm and (in parenthesis) in units of Schwarzschild radii; Column [4]: black hole mass in solar masses; Column [5]: size of the BLR in units of 10^{15} cm; Column [6]: power injected in the blob calculated in the comoving frame, in units of 10^{45} erg s^{-1} ; Column [7]: accretion disc luminosity in units of 10^{45} erg s^{-1} and (in parenthesis) in units of L_{Edd} ; Column [8]: magnetic field in G; Column [9]: bulk Lorentz factor at R_{diss} ; Columns [10] and [11]: break and maximum random Lorentz factors of the injected electrons; Columns [12] and [13]: slopes of the injected electron distribution $[Q(\gamma)]$ below and above γ_b ; and Column [14]: values of the minimum random Lorentz factor of those electrons cooling in one light crossing time. The total X-ray corona luminosity is assumed to be in the range 10–30 per cent of L_d . Its spectral shape is assumed to be always $\propto \nu^{-1} \exp(-h\nu/150 \text{ keV})$. The viewing angle θ_v is 3° for all sources.

Another implication is that, at lower energies, the $N(\gamma)$ distribution is proportional to γ^{-2} , while, above γ_b , $N(\gamma) \propto \gamma^{-(s_2+1)}$. The electrons emitting most of the observed radiation have energies γ_{peak} , which is close to γ_b (but these two energies are not exactly equal, due to the curved injected spectrum).

The accretion disc component is calculated assuming a standard optically thick and geometrically thin Shakura & Sunyaev (1973) disc. The emission is locally a blackbody. The temperature profile of the disc is given, for example, in Frank, King & Raine (2002). Since the optical–UV emission is the sum of the accretion disc and the jet non-thermal components, for a few sources, there is some degeneracy when deriving the black hole mass and the accretion rate.

We model at the same time the thermal disc (and IR torus) radiation and the non-thermal jet emission. The link between these two components is given by the amount of radiation energy density (as seen in the comoving frame of the emitting blob) coming directly from the accretion disc or reprocessed by the broad-line region (BLR) and the IR torus. This radiation energy density depends mainly on R_{diss} , but not on the adopted accretion rate or black hole mass (they are in any case chosen to reproduce the observed thermal disc luminosity).

By estimating the physical parameters of the source, we can calculate the power that the jet carries in the form of radiation (P_r), magnetic field (P_B), relativistic electrons (P_e) and cold protons (P_p), assuming one proton per electron. These powers are calculated according to

$$P_i = \pi R^2 \Gamma^2 c U'_i \quad (2)$$

where U'_i is the energy density of the i th component in the comoving frame.

4.1 Intervening Lyman α absorption

Being at $z > 2$, the optical–UV flux of the blazars in our sample could be affected by absorption of neutral hydrogen in intervening Lyman α absorption systems. To correct for this, we use the attenuation calculated in G10 specifically for the UVOT filters, illustrated in fig. 3 of that paper.

Full details of our calculation will be described in Haardt et al. (in preparation), together with a more refined treatment of the mean attenuation and its variance around the mean. The current procedure is very crude, especially when the attenuation is large (i.e. optical depths larger than unity), because in such cases, most of the attenuation is due to very few clouds, implying a large variance. However, we note that the variance of the attenuation is largely reduced when the actual filter width is taken into account (Madau 1995). Our absorption model results in a mean number of thick systems, which is less than one for $z \lesssim 4$, so we do not expect excessive offset of the attenuation along individual lines of sight with respect to the mean value.

When presenting the SED of our sources, we will show both the fluxes and upper limits dereddened for the extinction due to our Galaxy and the fluxes (and upper limits) obtained by de-absorbing them with the τ_{eff} shown in fig. 3 in G10.

5 RESULTS

Table 4 lists all parameters used to model the SEDs of our blazars, Table 5 lists the different forms of power carried by the jet and Figs 1–6 show the SEDs of the 19 blazars studied in this paper and the corresponding fitting model. In all figures, we have marked

Table 5. Logarithm of the jet power in the form of radiation (P_r), Poynting flux (P_B), bulk motion of electrons (P_e) and protons (P_p), assuming one proton per emitting electron). Powers are in erg s^{-1} . The bottom part of the table reports the data derived in G10 and G09.

with a grey-shaded area the *Fermi*/LAT sensitivity, bounded on the bottom by considering 1 yr of operation and a 5σ detection level and on the top by considering 3 months and a 10σ detection level (this assumes a common energy spectral index of $\alpha_\gamma \sim 1$, the sensitivity limit for other spectral indices is slightly different, see fig. 9 in A10). All these sources were not detected in the first 3 months, in fact the (11-month) γ -ray data points are very close to the lower boundary of the grey area. There are exceptions: 0106+01 (=4C+01.02) is brighter than the 3-month, 10σ sensitivity limits, even if it has not been included in the LBAS. This is due to a rather strong variability of the source, fainter in the first 3 months and brighter soon after. The same occurred for 1344–1723 and 0451–28. The opposite happened for 0227–369, 0347–211 and 0528+134 (i.e. they were brighter during the first 3 months), but their flux, averaged over 11 months, was in any case large enough to allow their inclusion in the 1LAC sample.

Some of the sources have a sufficiently good IR–optical–UV coverage to allow to see a peak of the SED in this band (see, for instance, 0420+022; 0451–28; 0458–02; 0625–5428; 0907+230; 0908+416; 1149–084; 1656–3302). The other sources have a SED consistent with a peak in this band, but the lack of data also allows for a peak at lower frequencies. We interpret the peak in the optical band as due to the accretion disc and assume its presence also in those blazars where it is allowed, but not strictly required. By assuming a standard Shakura–Sunyaev (1973) disc, we are then able to estimate both the black hole mass and the accretion rate. This important point has been discussed in G10, in Ghisellini et al. (2009b) (for S5 0014+813) and in Ghisellini & Tavecchio (2009).

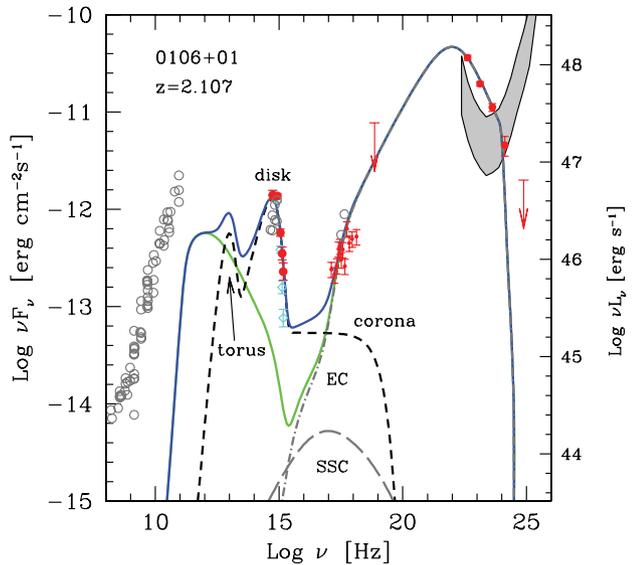

Figure 1. SEDs of 0106+01 ($=4C+01.02$) together with the fitting models, with parameters listed in Table 4. De-absorbed UVOT, XRT and BAT data are indicated by darker symbols (red in the electronic version), while archival data (from NED) are shown in light grey. Diamonds (and lower arrows, cyan in the electronic version) indicate UVOT data not de-absorbed by intervening Lyman α clouds. The short-dashed line is the emission from the IR torus, the accretion disc and its X-ray corona. The solid thin (green) line is the non-thermal emission [sum of synchrotron, synchrotron self-Compton (SSC) and the External Compton (EC)]. The long-dashed and the dot-dashed grey lines represent the SSC and the EC components, respectively. The thick solid (blue) line is the sum of all components. The grey stripe in the γ -ray band corresponds to the *Fermi*/LAT sensitivity of the first 3 months (10σ , upper boundary) and for 11 months (4σ , lower boundary).

The radio data cannot be fitted by a simple one-zone model specialized to fit the bulk of the emission, since the latter must be emitted in a compact region, whose radio flux is self-absorbed up to hundreds of GHz. The radio emission should come from larger regions of the jet. On the other hand, when possible, we try to have some ‘continuity’ between the non-thermal model continuum and the radio fluxes (i.e. the model, in its low-frequency part, should not lie at too low or too high fluxes with respect to the radio data). In the following, we briefly comment on the obtained parameters:

Dissipation region. The distance R_{diss} at which most of the dissipation takes place is one of the key parameters for the shape of the overall SED, since it controls the amount of energy densities as seen in the comoving frame (see Ghisellini & Tavecchio 2009). For almost all sources, we have $R_{\text{diss}} < R_{\text{BLR}}$, while for 0106+01, 0907+230, 1343+451, 1344–1723 and 1959–4246, R_{diss} is slightly larger than R_{BLR} , and for 0743+259 $R_{\text{diss}} \sim 2R_{\text{BLR}}$.

In all sources, the dominant cooling is through inverse Compton off the seed photons of the BLR. This is true also for the few blazars in which $R_{\text{diss}} \geq R_{\text{BLR}}$, since, even if U'_{BLR} seen in the comoving frame is smaller, U_B is smaller, implying that the ratio U'_{BLR}/U_B is similar to the values in other sources [U'_{BLR}/U_B ranges between ~ 30 (1344–1723) and ~ 100 (0106+01, 0907+230)]. However, the decreased cooling rate in 0743+259 makes γ_c to be larger ($\gamma_c = 102$, see Table 4).

With still larger $R_{\text{diss}} \gg R_{\text{BLR}}$, the main seed photons for the Compton scattering process would become the photons produced by the IR torus (if it exists), but this case does not occur for our sources.

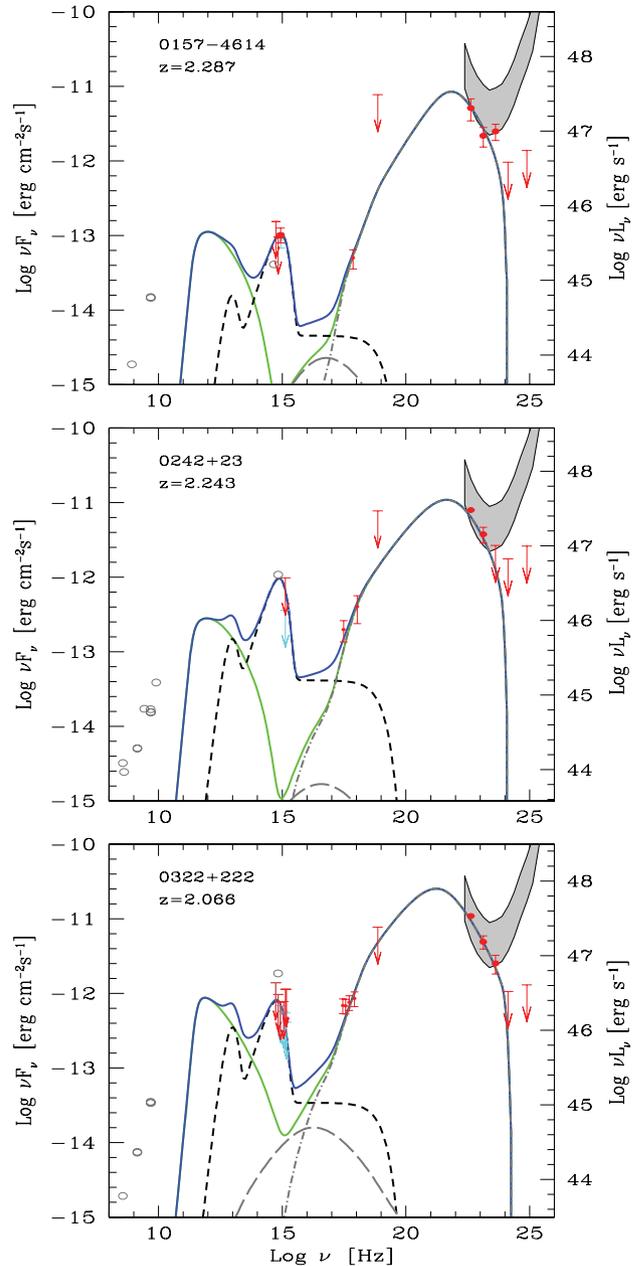

Figure 2. SED of PMN 0157–4614, B2 0242+23 and TXS 0322+222. Symbols and lines as in Fig. 2.

Compton dominance. This is the ratio between the luminosity emitted at high frequencies and the synchrotron luminosity. The average magnetic field is found to be of the order of 1 G, with a corresponding magnetic energy density that is around two orders of magnitude lower than the radiation energy density. Correspondingly, all sources are Compton dominated.

Black hole masses. Fig. 7 shows the distribution of black hole masses for the 28 blazars at $z > 2$ and compares them with the distribution of masses for the high-redshift BAT blazars. Although the black hole masses of the BAT sample extend to larger values, there are still too few sources to estimate if the two distributions are different. It is interesting to note that all but three sources (0420+022, 0907+230 and 2135–5006) have black hole masses greater than $10^9 M_{\odot}$. In Ghisellini, Tavecchio & Ghirlanda (2009c), we considered the *Fermi* blazars of γ -ray luminosity $L_{\gamma} > 10^{48}$ erg s^{-1} ,

finding, with the same method and model applied here, that for all these sources, the black hole mass was greater than a billion solar masses. Therefore, *all* blazars with $L_\gamma > 10^{48}$ erg s $^{-1}$ have black holes heavier than $10^9 M_\odot$, while the vast majority, but not all, blazars at $z > 2$ have such large black hole masses. We searched in the literature other estimates of the black hole masses for the objects in this sample, finding $M = 2.3 \times 10^9 M_\odot$ for 0836+710 (estimated by Liu, Jiang & Gu 2006), and other few limits for the black hole masses for 0836+710 and 0528+134, which were, however, based assuming an isotropic γ -ray emission.

Disc luminosities. We are considering very powerful blazars, so we do expect large disc luminosities, not only on the basis of an expected positive trend between the observed non-thermal (albeit

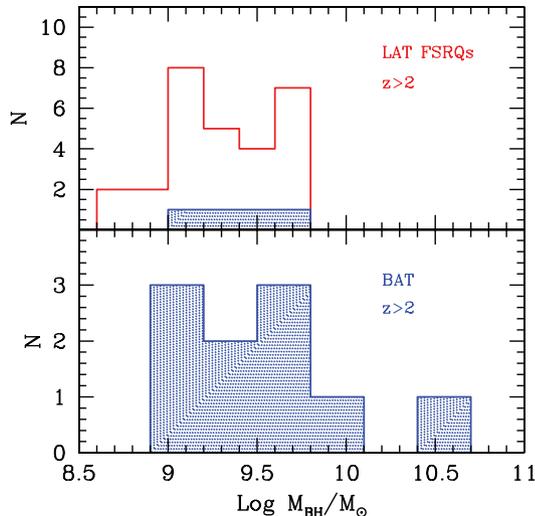

Figure 7. Distribution of the black hole masses derived for the $z > 2$ *Fermi*/LAT (top panel) and *Swift*/BAT samples (bottom panel). The hatched area in the top panel corresponds to the four blazars in common.

beamed) and the accretion luminosities, but also on the basis of the observed luminosities of the broad lines, that should linearly depend on the accretion power. What is interesting is that all the FSRQs analysed up to now (i.e. belonging to the LBAS or to the subset of high-redshift 1LAC and BAT samples) have a ratio L_d/L_{Edd} between 10^{-2} and 1. This can be seen in the middle panel of Fig. 8, which shows L_d as a function of the derived black hole mass. The two dashed lines correspond to the Eddington and 1 per cent Eddington luminosities. This confirms the idea of the ‘blazars’ divide’ as a result of changing the accretion mode (Ghisellini, Maraschi & Tavecchio 2009a): from the standard Shakura–Sunyaev (appropriate for all FSRQs) to the Advanced Dominated Accretion Flow (ADAF)-like regime (appropriate for BL Lacs). The $z > 2$ blazars analysed here have L_d/L_{Edd} ratios ranging from 0.05 and 0.7. The exact values of the disc luminosities derived here are the frequency-integrated bolometric luminosities of the assumed Shakura–Sunyaev accretion disc model that best interpolates the data. On the other hand, any other accretion disc model has to fit the data as well, implying that our values of L_d are robust, and nearly model-independent, within the limit of the uncertainties of the observed data.

Jet powers. The values listed in Table 5 are very similar to the values derived for other powerful *Fermi* FSRQs. They are not, however, the absolutely greatest powers found. This can be seen in the bottom panel of Fig. 8, showing P_{jet} as a function of the black hole mass, and in the middle and bottom panels of Fig. 9, where we plot the power of the jet spent in the form of radiation (P_r) and the total jet power P_{jet} as a function of L_d . We can compare the $z > 2$ 1LAC FSRQs with those present in the LBAS catalogue and the high-redshift BAT blazars. Not surprisingly, we see that in these planes, the 1LAC $z > 2$ sources follow the distribution of the most-luminous γ -ray blazars. Remarkably though, the $z > 2$ BAT FSRQs appear to lie at the extreme of the distributions, being the more powerful in L_d , and among the most powerful in P_r and P_{jet} . For calculating the power carried by the jet in the form of protons, we reiterate that we have assumed one cold proton per emitting electron: if there exist a population of cold electrons, and no electron–positron pairs, then we underestimate P_p and then P_{jet} , while if there are no cold leptons, but there are pairs, then we overestimate P_p . Finally, protons are assumed cold for simplicity (and ‘economy’), but they could be hot

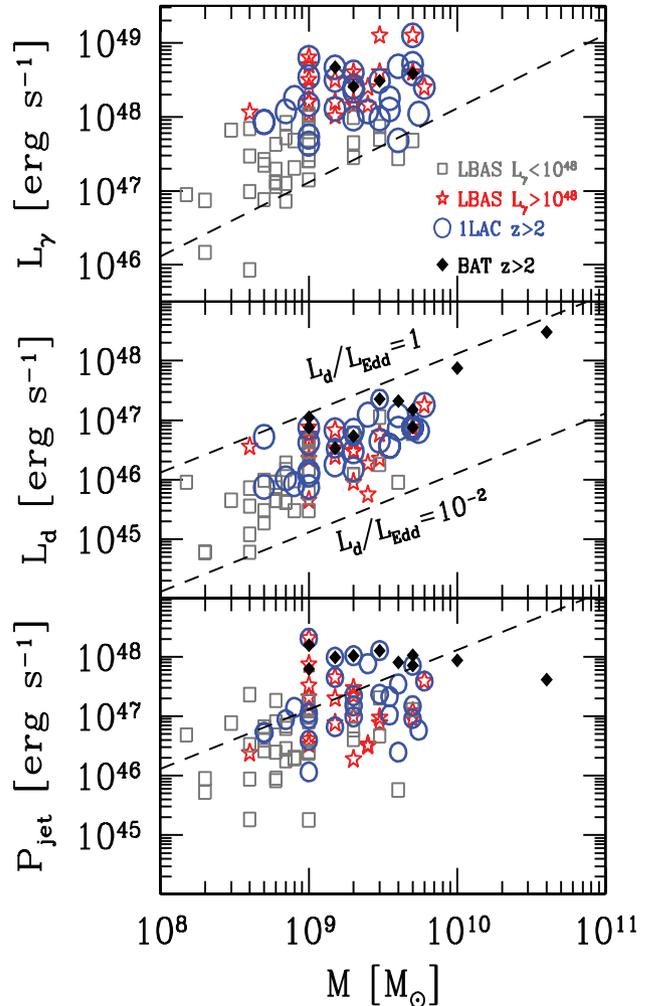

Figure 8. The observed γ -ray luminosity in the 0.1–10 GeV band, the accretion luminosity L_d and the total jet power P_{jet} as a function of the derived black hole mass. All points correspond to FSRQs. Different symbols correspond to LBAS FSRQs with $L_\gamma > 10^{48}$ erg s $^{-1}$ (red stars, analysed in Ghisellini et al. 2009b); 1LAC FSRQs with $z > 2$ (empty blue circles); BAT FSRQs with $z > 2$ (black diamonds, G10); and the LBAS FSRQs with $L_\gamma < 10^{48}$ erg s $^{-1}$ (grey squares, Ghisellini et al. 2010b). The γ -ray luminosity (top panel) is the observed beamed one and it has not to be confused with P_r , the power spent by the jet to produce the radiation we see. The middle panel shows that all FSRQs have disc luminosities between 0.01 and 1 Eddington luminosity. The bottom panel shows that P_{jet} can be larger (but not by a big factor) than the Eddington luminosity corresponding to the dashed line.

or even relativistic (if e.g. shocks accelerate not only electrons but also protons), and in such cases, the power is underestimated. For a detailed discussion about the presence of electron–positron pairs in blazars’ jets, we refer to the discussions in Sikora & Madjesi (2000), Celotti & Ghisellini (2008) and G10, where one can find arguments limiting the amount of pairs in the jet. A few electrons–positrons per proton are possible, but not more.

Jet powers versus accretion luminosities. Fig. 9 shows that the correlations found in G10 between P_r and/or P_{jet} and L_d are confirmed. We remind the reader that P_r and L_d are independent quantities, even if the main radiation mechanism is the inverse Compton process using broad-line photons as seeds that, in turn, are proportional to the accretion disc luminosity. This is because the radiative cooling of the emitting electrons is complete, implying that the

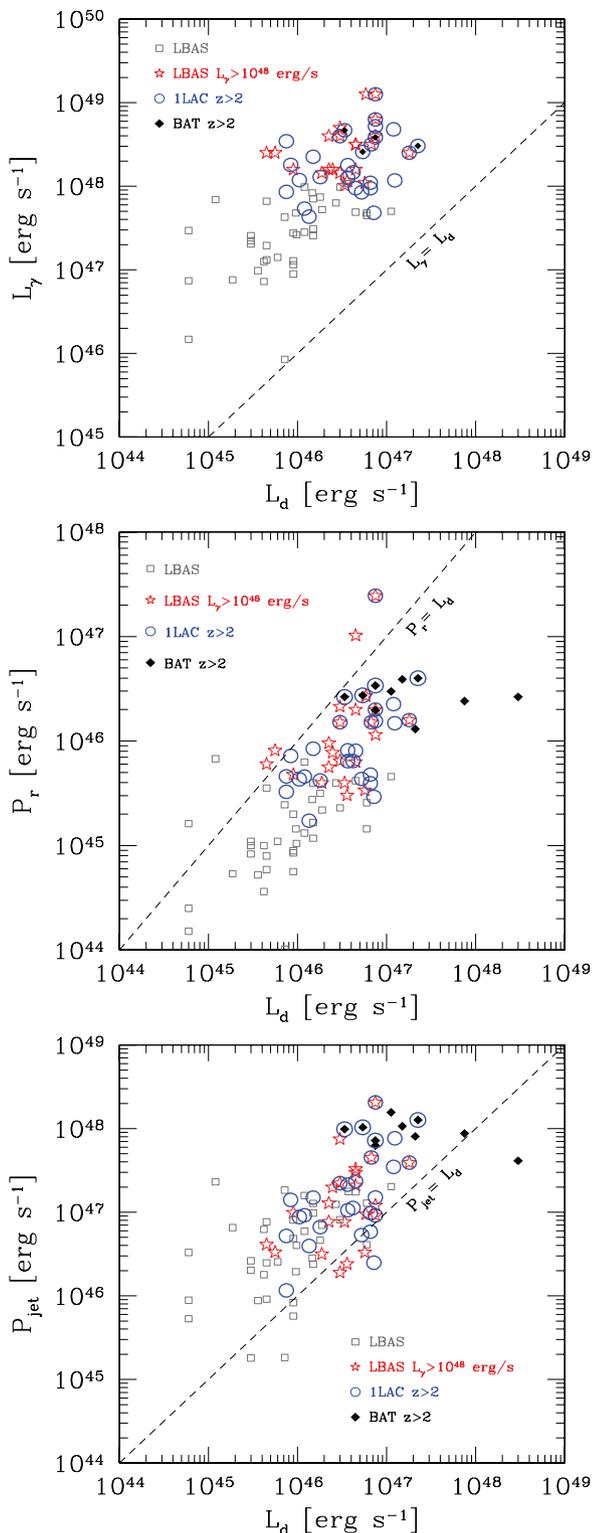

Figure 9. Top panel: the observed γ -ray luminosity L_γ as a function of the accretion luminosity L_d for the LBAS FSRQs (grey squares), the $z > 2$ 1LAC (blue circles) and *Swift*/*BAT* (diamonds) FSRQs. The dashed line indicates $L_\gamma = L_d$. Middle panel: the power P_r as a function of L_d . P_r can be considered as a robust and almost model-independent lower limit to the jet power. Bottom panel: the total jet power $P_{\text{jet}} = P_B + P_e + P_p$ as a function of L_d . Almost all sources have $P_{\text{jet}} > L_d$. One cold proton per emitting electron is assumed.

produced jet luminosity becomes independent of the amount of radiation energy density. In other words, in the fast-cooling regime, the jet always emits all the energy of its relativistic electrons, irrespective of the amount of luminosity of the accretion disc.

A least-squares fit returns a chance probability $P = 4 \times 10^{-8}$ that $\log P_r$ and $\log P_{\text{jet}}$ are correlated with $\log L_d$ (and the correlations are consistent with being linear). They remain significant also when considering the common redshift dependence, although the chance probability increases to $P = 4 \times 10^{-4}$ (for the P_r - L_d correlation) and to $P = 10^{-3}$ (for the P_{jet} - L_d correlation).

As expected, the 1LAC blazars at high redshifts are among the most powerful, even if there are blazars at lower redshifts with comparable powers. This can be seen by comparing the empty circles, corresponding to the 1LAC blazars of our sample, with the LBAS FSRQs of $L_\gamma > 10^{48}$ erg s^{-1} (stars) and the BAT FSRQs at $z > 2$ (black diamonds). There are a few sources with $P_r > L_d$ and several with $P_r \sim L_d$. The jet in these blazars, only to produce the radiation we see, requires a power comparable to (or even larger than) the disc luminosity. The P_r power should be considered a very robust estimate of the *minimum* jet power: it is robust, because it is almost model-independent ($P_r \sim L_\gamma / \Gamma^2$, see G10), and it is a lower limit, because it corresponds to the entire jet power being converted into radiation at the γ -ray-emitting zone. Indeed, if there is one proton per emitting electron, the total jet power, dominated by the bulk motion of cold protons, becomes a factor of ~ 10 larger than L_d (bottom panel of Fig. 9), with the FSRQs of our sample distributed in a large portion of the P_{jet} - L_d plane.

We believe that the relation between both P_r and P_{jet} with L_d is a key ingredient to understand the birth of jets: accretion *must* play a key role.

Comparison with other models. Several groups (Larionov et al. 2008; Marscher et al. 2008, 2010; Sikora, Moderski & Madejski 2008) proposed that the emitting region, especially during flares, is produced at distances from the central black hole of the order of 10–20 pc (much larger than what we assume) at the expected location of a reconfinement shock (e.g. Sokolov, Marscher & McHardy 2004). On the basis of an observed peculiar behaviour of the polarization angle in the optical, Marscher et al. (2008) thus suggested that blobs ejected from the central region are forced by the magnetic field to follow a helical path, accounting for the observed rotation of the polarization angle in the optical. Flares (at all wavelengths) correspond to the passage of these blobs through a standing conical shock, triggered by the compression of the plasma in the shock. This has important consequences for the variability of the emission: since the emission region is located at large distances from the central engine, its size is large and the expected variability time-scale cannot be very short. Assuming $R_{\text{diss}} = 15$ pc, a jet aperture angle of $\theta_{\text{jet}} = 3^\circ$ and $\delta = 20$, we find a minimum variability time-scale of $t_{\text{var}} = \theta_{\text{jet}} R_{\text{diss}} (1+z) / (c\delta)$ of the order of $1.5(1+z)$ months, which for sources at $z > 2$ implies a minimum variability time-scale of 5–6 months. The main high-energy emission mechanism is still the inverse Compton process, using as seeds the IR radiation of a surrounding torus (Sikora et al. 2008) with a possible important contribution from jet synchrotron radiation (Marscher et al. 2008, 2010). The main difficulty of these models concerns the expected variability, predicted to occur on a very long time-scale, if the size of the emitting region is proportional (through e.g. the opening angle of the jet) to the distance of the source to the black hole. Instead, the observed γ -ray flux in all strong γ -ray sources (the ones for which a reliable variability behaviour can be established) varies on much shorter time-scales and a factor of 2 flux changes can occur even on 3–6 h (see Tavecchio et al. 2010 for 3C 454.3

and PKS 1510–089; Bonnoli et al. 2010; Foschini et al. 2010 and Ackermann et al. 2010 for 3C 454.3; Abdo et al. 2009b for PKS 1454–354; Abdo et al. 2010c for PKS 1502+105). This indicates that the source is compact. This in turn suggests (although it does not prove) that its location cannot be too far from the black hole. It then also suggests that it is within the BLR. In turn, this suggests that the broad lines are the main seeds for the inverse Compton scattering process. Occasionally, though, dissipation could occur farther out, where the main seeds are the IR photons produced by a putative torus surrounding the accretion discs. Since the seed photons have smaller frequencies, in these cases, the produced high-energy spectrum suffers less from possible effects of the decreasing (with seed frequencies) scattering Klein–Nishina cross-section and from possible photon–photon interactions leading to electron–positron pair production. The decreased importance of both effects may account for high-energy spectra extending, unbroken, up to hundreds of GeV. These cases should be characterized by a longer variability time-scale.

In the model of Marscher et al. (2008), a very short variability time-scale still indicates a very compact emitting region, but nevertheless located at a large distance from the central black hole.

5.1 Comparing BAT and LAT high-redshift blazars

Both the 1LAC sample and the BAT 3-yr survey have a rather uniform sky coverage, and both approximate a flux limited sample. The 1LAC sample has a limiting flux sensitivity that depends on the γ -ray spectral index of the sources, but since we are dealing with FSRQs only (whose α_γ is contained in a relatively narrow range), we can consider this sample as flux limited. It is then interesting to compare the high-redshift blazars (all of them are FSRQs) contained in the two samples. We remind that for blazars with $z > 2$, we have 10 FSRQs in the BAT sample, 28 in the 1LAC and four in both. The X-ray-to- γ -ray SED of these sources is very similar: even if we have only four blazars in common, for all sources, the SED has a high energy peak in the \sim MeV–100 MeV band, with $\alpha_X < 1$ and $\alpha_\gamma > 1$.

Thus, the spectrum can be approximated by a broken power law. For illustration, consider the smoothly broken power law of the form

$$L(\nu) \propto \frac{(\nu/\nu_b)^{-\alpha_X}}{1 + (\nu/\nu_b)^{\alpha_\gamma - \alpha_X}}. \quad (3)$$

If the energy indices $\alpha_X < 1$ and $\alpha_\gamma > 1$, the peak is at $\nu_{\text{peak}} = \nu_b[(1 - \alpha_X)/(\alpha_\gamma - 1)]^{1/(\alpha_\gamma - \alpha_X)}$. With this function, we can easily calculate the ratio of the BAT (15–55 keV) to LAT (0.1–100 GeV) luminosities as a function of ν_{peak} and see if it compares well to the data. We alert the reader that by ‘data’ we mean real observed data when the source has been detected in the X-ray and γ -ray band, while, when the detection is missing, we mean the ‘data’ coming from our fitting model described in Section 4 (and in more detailed in Ghisellini & Tavecchio 2009).

The ratio L_X/L_γ , as a function of ν_{peak} , calculated using equation (3) setting $\alpha_X = 0.5$ and $\alpha_\gamma = 1.6$ is plotted in Fig. 10 as a grey (orange in the electronic version) line, together with the points corresponding to high-redshift blazars studied in this paper and in G10. Furthermore, Fig. 10 reports also the data of all the LBAS blazars studied in Ghisellini et al. (2010b). These are FSRQs (filled grey circles) and BL Lacs (empty grey squares). In the top panel, ν_{peak} is in the rest frame of the source, while in the bottom panel, ν_{peak} is the observed one.

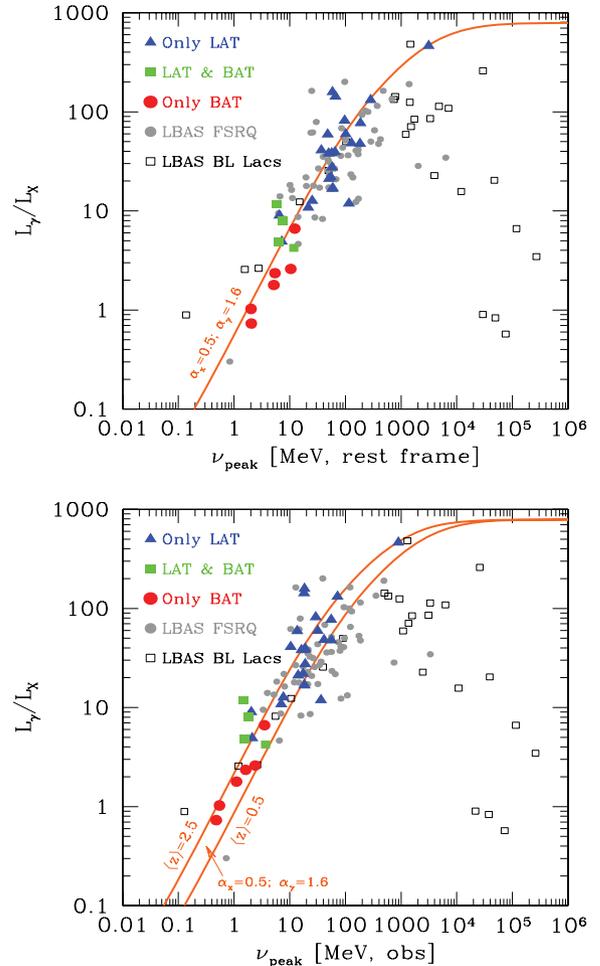

Figure 10. Top panel: the ratio of the (rest-frame) luminosities in the 0.1–100 GeV and 15–55 keV bands as a function of the rest-frame peak frequency of the high-energy bump. For sources not detected in one of the two bands, we have used the corresponding flux resulting from the modelling of their overall SED. Different symbols are from the sources detected only by *Fermi*/LAT, by both *Swift*/BAT and *Fermi*/LAT and only by *Swift*/BAT, as labelled. For comparison, we also show all FSRQs (grey dots) and BL Lacs (squares) in the LBAS. The continuous line shows the estimate using the smoothly broken power-law function (see text) with $\alpha_X = 0.5$ and $\alpha_\gamma = 1.6$. Bottom panel: the same, but plotting observed peak frequencies. The continuous lines are for $z = 2.5$ and $z = 0.5$. See how the simple function in equation (3) interpolates well the data of FSRQs. The X-ray and γ -ray SEDs of BL Lacs, instead, are not due to a single radiation process, since the hard X-rays are often due to the tail of the synchrotron emission. As a consequence, they show behaviour opposite to FSRQs: a smaller L_X/L_γ ratio with increasing ν_{peak} , indicating an increasingly stronger contribution of the synchrotron flux to the hard X-ray band.

Fig. 10 shows a remarkable agreement between the FSRQ data and the simple broken power law of equation (3), both for high-redshift and for less-distant FSRQs. BL Lac objects, instead, are not well represented by equation (3). In fact, in many BL Lacs, the hard X-rays correspond to the (steep) tail of the synchrotron component. Therefore, the X-rays and the γ -rays are produced by two different mechanisms and equation (3) does not represent their overall high-energy SED. In BL Lacs, the importance of X-rays *increases* with increasing ν_{peak} , because of the increasing importance of synchrotron flux in the hard X-rays.

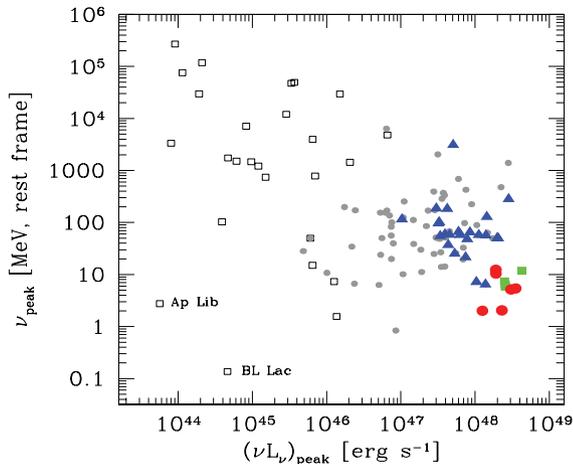

Figure 11. The rest-frame peak frequency ν_{peak} of the high-energy emission as a function of the $\nu_{\text{peak}} L_{\nu_{\text{peak}}}$ luminosity. Symbols as in Fig. 10. A clear trend can be seen when considering BL Lacs and FSRQs together, while only FSRQs are characterized by a very large dispersion. High-redshift FSRQs occupy the region of the largest luminosities and smallest ν_{peak} . We indicate the two ‘outliers’: BL Lac and Ap Lib.

Coming back to high-redshift FSRQs, only four sources have detection in both bands, while 24 FSRQs are detected only by the LAT and six only by the BAT instrument. Our model explains the large fraction of sources that are detected only in one of the two instruments as due to the different values of ν_{peak} of the sources: if ν_{peak} is large (above 10 MeV), F_{γ}/F_X is large and the source is relatively weak in the the BAT band, while if $\nu_{\text{peak}} < 10$ MeV, the source becomes relatively weak in the LAT band and strong in the BAT band.

It is interesting to see if the derived ν_{peak} correlates with the bolometric luminosity. Fig. 11 shows that a trend indeed exists: more powerful sources have smaller ν_{peak} (we have used $\nu_{\text{peak}} L_{\nu_{\text{peak}}}$ as a proxy for the bolometric luminosity). However, comparing with all the LBAS FSRQs (grey dots), we see that the $z > 2$ luminous FSRQs belong to a broader (i.e. more scattered) distribution and that the high-redshift BAT blazars are really the most extreme.

We can conclude that (i) there is a trend between the high energy peak and the peak luminosity, (ii) this correlation has a large scatter, even if the $z > 2$ FSRQs show the same trend with less scatter (but this may be due to the still small number); and (iv) the $z > 2$ blazars in the 3-yr BAT survey all lie in the highest luminosity, smallest ν_{peak} part of the plane.

When more BAT detections of high-redshift LAT blazars will become available (and, conversely, when the LAT will detect more BAT high-redshift blazars), this trend can be tested directly (i.e. without modelling the SED). The importance of this is two-fold: first, we can estimate in a reasonable way the peak energy of the high-energy emission having the hard X-ray and the γ -ray luminosities, and secondly (and more important), we could conclude that the most-powerful blazars can be more easily picked up through hard X-ray surveys, as the one foreseen with the *EXIST* mission (Grindlay et al. 2010).

6 SUMMARY AND DISCUSSION

The total number of $z > 2$ blazars with high-energy information is 34 (28 with a LAT detection, six with a BAT detection and four with both). It is still a limited number, the tip of the iceberg of a much larger (and fainter) population, but it is derived from

two well-defined samples (LAT and BAT) that we can consider as flux limited and coming from two all-sky surveys (excluding the Galactic plane). The main result of studying them is that all the earlier findings concerning the physical parameters of the jet-emitting zone, the jet power and the correlation between the jet power and the disc luminosity are confirmed.

They are in agreement with the blazar sequence, that is, their non-thermal SEDs are ‘redder’ than less-luminous blazars, with a large dominance of their high-energy emission over the synchrotron one. This implies that the disc emission is left unhidden by the synchrotron flux and this allows an estimation of the black hole mass and the accretion rate. The uncertainties associated with these estimates are relatively small within the assumption that the thermal component is produced by a standard Shakura–Sunyaev disc with an associated non-spinning hole. In G10, we argued that in any case the masses are not largely affected by this assumption and, in particular, that in the Kerr case, the derived masses are not smaller, despite the greater accretion efficiency. The possibility of an intrinsic collimation of the disc radiation appears more serious. If the disc is not geometrically thin, but, for example, a flared disc, then we expect a disc emission pattern concentrated along the normal to the disc, that is, along the jet axis. We previously argued (Ghisellini et al. 2009b) that this can be the case of S5 0014+813 at $z = 3.366$, an extraordinary luminous blazar (detected by the BAT) with an estimated ‘outrageous’ black hole mass of $4 \times 10^{10} M_{\odot}$, and indeed we found it to be an ‘outlier’ in the P_r-L_d plane. Reverting the argument, it implies that the other FSRQs, obeying a well-defined P_r-L_d trend, should have disc luminosities with a quasi-isotropic pattern, that is, standard, not flaring, discs. The other severe uncertainty on the mass estimation for objects at large redshifts is the amount of attenuation of their optical–UV flux due to intervening Lyman α clouds. We have corrected for this assuming an average distribution of clouds, and when the attenuation is due to a few thick clouds, the expected variance is large. While we plan to refine such estimates (Haardt et al., in preparation), it is unlikely that this implies a systematic error on the mass estimates, leading to larger values: statistically, the mass distribution should not be seriously affected by this uncertainty.

Although affected by the same issues outlined above, also the correlation between the jet power and the disc luminosity should resist when a more refined treatment of the Lyman α absorption will be available, by the same arguments. Therefore, we can conclude that the accretion rate is really a fundamental player in powering the relativistic jet and we refer the reader to Ghisellini et al. (2010b) for a detailed discussion about this finding. If true, these ideas lead us to suggest that powerful, high-redshift ‘true’ (i.e. really lineless) BL Lacs do not exist.

Another, at first sight surprising, result of our study is that the correlation between the peak frequency of the high-energy emission and the γ -ray luminosity at this peak frequency exists also for the $z > 2$, highly luminous FSRQs. It is surprising, because in very powerful sources, the radiative cooling is complete (i.e. all electrons with γ larger than a few cool in one light crossing time). Therefore, the electrons responsible for the peak have energies that are not fixed by radiative cooling, but by the injection function [i.e. by the $Q(\gamma)$ function given in equation (1) and, more precisely, by the value of γ_b]. On the other hand, when considering all blazars in the LBAS, we see that the scatter, for large luminosities, is much larger, so the apparent correlation for the $z > 2$ blazars can be due to small statistics. Clearly, it is a point to investigate further.

It is interesting to ask what will be the best strategy to find the most-luminous FSRQs at the largest redshifts. The interest lies in

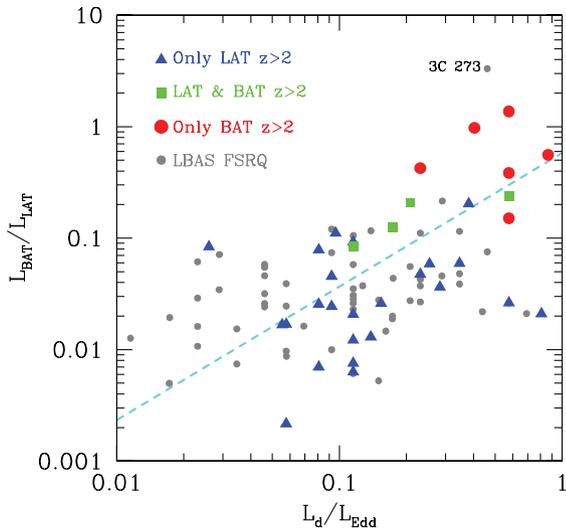

Figure 12. The ratio between the luminosities in the BAT and LAT energy ranges (i.e. 15–55 keV and 0.1–10 GeV) as a function of the disc luminosity, in Eddington units. The big dots are the six BAT blazars in the $z > 2$ sample not detected (yet) by *Fermi*/LAT, squares are BAT blazars of the same sample already present in the ILAC sample, triangles are the sources discussed in this paper and the small grey dots are all the FSRQs present in the LBAS discussed in G10. The dashed line is the best least-squares fit (chance probability $P = 2 \times 10^{-6}$).

the link between the jet power and disc luminosity: finding the most-powerful jets implies to find the most accreting systems, hence the heaviest black holes. Since for each source pointing at the Earth (i.e. a blazar) there must exist $\sim 2\Gamma^2$ similar sources pointing in other directions, the finding of even a few blazars at large redshifts with a large black hole mass can put very interesting constraints on the black hole mass function of jetted sources. This issue has been discussed by us previously (G10) and we suggested that the existence of the blazar sequence, plus an important K-correction effect, makes the hard X-ray range the best band where to search for the high-redshift heaviest black holes. Here, we reiterate this suggestion offering a supplementary information. For each analysed FSRQ (belonging to the LBAS or in this paper), we have calculated the ratio between the expected BAT luminosity (15–55 keV, rest frame) and the observed (0.1–100 GeV, rest frame) LAT luminosity. This ratio is not an observed quantity, since very few FSRQs (in comparison with the LAT) have been detected by the BAT, but it is a result of the model. With the same model, we have then calculated the disc luminosity in units of Eddington. Fig. 12 shows the $L_{\text{BAT}}/L_{\text{LAT}}$ ratio as a function of L_d/L_{Edd} . We have marked with different symbols the FSRQs analysed in this paper and the ones analysed previously (G10). We have excluded BL Lacs for which we have only an upper limit on the disc luminosity. Fig. 12 suggests a clear trend (albeit with some scatter): FSRQs accreting close to Eddington emit relatively more in the hard X-rays than above 100 MeV. Formally, a least-squares fit returns $(L_{\text{BAT}}/L_{\text{LAT}}) \propto (L_d/L_{\text{Edd}})^{1.2}$ with a chance probability $P = 2 \times 10^{-6}$ (for 95 objects). This implies that hard X-ray surveys benefit from a positive bias when looking for blazars with black holes accreting close to Eddington. In turn, at high redshifts, this implies the finding of the heaviest black holes, since it is very likely that at those early epochs (e.g. $z > 2$), all black holes are accreting close to the Eddington rate.

7 CONCLUSIONS

We summarize our main conclusions as follows:

- (i) The blazars detected by *Fermi* at $z > 2$ are all FSRQs, with typical ‘red’ SEDs.
- (ii) These FSRQs are very luminous and powerful, but they are not at the very extreme of the distribution of the luminosity and jet power.
- (iii) These sources have heavy black holes ($M \sim 10^9 M_\odot$) and accretion luminosities greater than ~ 10 per cent Eddington. When including all FSRQs in the LBAS, irrespective of the redshift, the accretion disc luminosities are greater than 1 per cent Eddington.
- (iv) The trend of redder SEDs when more luminous (i.e. one of the defining characteristics of the blazar sequence) is confirmed and it is even present within the relatively small range of observed luminosities of the $z > 2$ blazars.
- (v) The correlation between the jet power and the disc luminosity is confirmed and points to a crucial role played by accretion in powering the jet.
- (vi) FSRQs with accretion discs closer to the Eddington luminosity have jets emitting a ‘redder’ SED and therefore can be more efficiently picked up by hard X-ray surveys (such as the one foreseen by *EXIST*), rather than by surveys in the hard γ -ray band.

ACKNOWLEDGMENTS

This work was partly financially supported by an ASI I/088/06/0) grant. This research made use of the NASA/IPAC Extragalactic Data base (NED), which is operated by the Jet Propulsion Laboratory, Caltech, under contract with the NASA, and of the *Swift* public data made available by the HEASARC archive system. We also thank the *Swift* team for quickly approving and performing the requested ToO observations.
