ABSTRACT

Context. The Seyfert 1.8 galaxy ESO 113-G010 had been observed for the first time above 2 keV by XMM-Newton during a short exposure (~4 ks) in May 2001. In addition to a significant soft X-ray excess, it showed one of the strongest (in *EW*) redshifted Fe K α lines, at 5.4 keV.

Aims. We present here a long (100 ks) XMM-Newton follow-up of this source performed in November 2005, in order to study over a longer time-scale its main X-ray properties.

Methods. We use both timing analysis (Power Spectra Density analysis, rms spectra, flux-flux analysis) and spectral analysis which mainly focuses on the Fe K α line complex.

Results. The source was found in a higher/softer time-averaged flux state, and timing analysis of this source reveals strong, rapid variability. The Power Spectral Density (PSD) analysis indicates (at 95% confidence level) a break at $3.7^{+1.0}_{-1.7} \times 10^{-4}$ Hz. This cut-off frequency is comparable to those measured in some other rapidly-variable Seyferts, such as MCG-6-30-15 and NGC 4051. From the mass-luminosity-time-scale, we infer that M_{BH} ranges from 4×10^6 – $10^7 M_{\odot}$ and the source is accreting at or close to the Eddington rate (or even higher). The existing data cannot distinguish between spectral pivoting of the continuum and a two-component origin for the spectral softening, primarily because the data do not span a broad enough flux range. In the case of the two-component model, the fractional offsets measured in the flux-flux plots increase significantly toward higher energies (similar to what is observed in MCG-6-30-15) as expected if there exists a constant reflection component. Contrary to May 2001, no significant highly redshifted emission line is observed (which might be related to the source flux level), while two narrow emission lines at about 6.5 keV and 7 keV are observed. The *S/N* is not high enough to establish if the lines are variable or constant. As already suggested by the 2001 observation, no significant constant narrow 6.4 keV Fe K α line (*EW* ≤ 32 eV) is observed, hence excluding any dominant emission from distant cold matter such as a torus in this Seyfert type 1.8 galaxy.

Key words. galaxies: Seyfert – galaxies: active – X-rays: galaxies – accretion, accretion disks – quasars: individual: ESO 113-G010

1. Introduction

The Seyfert ESO113-G010 ($z = 0.0257$) was observed for the first time in X-rays, in December 1995, by *ROSAT*, revealing an X-ray luminosity of about 2.5×10^{43} erg s⁻¹ (assuming $H_0 = 75$ km s⁻¹ Mpc⁻¹ and $q_0 = 0.5$) and some indication of X-ray variability (Pietsch et al. 1998). An optical follow-up (2.2 m ESO/MPG telescope at la Silla) performed in November 1996 done by the same authors to characterize this bright galaxy led to the conclusion that this Seyfert is of type 1.8, and measured $\log L_{\text{FIR}} = 44.34$ erg s⁻¹, $\log L_{\text{B}} = 43.97$ erg s⁻¹, and $\log L_{\text{X, ROSAT}} = 43.40$ erg s⁻¹. This object was observed for the first time above 2 keV with *XMM-Newton* on May 3, 2001 during a short exposure of about 4 ks. That observation revealed a soft excess below 0.7 keV and, more interestingly, a narrow emission line at 5.4 keV (rest-frame), most probably originating from a

redshifted iron Fe K α line (Porquet et al. 2004b). The line was detected at 99% confidence, calculated via Monte Carlo simulations which fully account for the range of energies where a narrow iron line is likely to occur. Such narrow spectral features in the 5–6 keV energy range were discovered with *XMM-Newton* and *Chandra* in several other AGN: e.g. NGC 3516 (Turner et al. 2002), NGC 7314 (Yaqoob et al. 2003), Mkn 766 (Turner et al. 2004), AX J0447-0627 (Della Ceca et al. 2005). The redshifted Fe K α line discovered in ESO 113-G010 had an *EW* of ~265 eV, making it one of the strongest (in *EW*) redshifted iron lines observed to date in an AGN. The energy of the redshifted line could indicate emission from relativistic (0.17–0.23 c) ejected matter moving away from the observer, as proposed for Mrk 766 by Turner et al. (2004). Alternatively, if the classification as type 1.8 object is correct, then emission from a narrow annulus at the surface of the accretion disc is unlikely due to the very small

inclination angle (i.e. less than 10°) required to explain the narrow, redshifted line in this intermediate Seyfert galaxy. However, emission from a small, localized hot-spot on the disc, occurring within a fraction of a complete disc orbit, could also explain the redshifted line (e.g., Turner et al. 2002; Dovčiak et al. 2004).

Here, we present a 100 ks *XMM-Newton* follow-up observation of ESO 113-G010. In Sect. 2, we present the long *XMM-Newton* analysis performed in November 2005, and the corresponding data reduction used for this work. Section 3 presents the timing analysis: light curves, PSD analysis, rms-spectrum, and flux-flux analysis. Section 4 presents the spectral analysis, focusing on the study of the Fe $K\alpha$ line complex between 6.4–7 keV. Finally, we summarize and discuss the main results of the present work (Sect. 5).

2. XMM-Newton observation and data reduction

XMM-Newton observed ESO 113-G010 starting on November 10, 2005 (orbit 1085) with exposure times of ~ 103 ks and ~ 102 ks for the MOS, and PN respectively. The EPIC-MOS cameras (Turner et al. 2001) operated in the Large Window mode, while the EPIC-PN camera (Strüder et al. 2001) operated in the standard Full Frame Window mode. Background flaring was negligible during most of the observation and therefore the whole observation was used, except when mentioned in Sect. 3. The EPIC data were re-processed and cleaned using the *XMM-Newton* SAS VERSION 6.5.0 (Science Analysis Software) package. The net resulting livetimes were 102.1 ks and 90.6 ks respectively for the MOS and PN cameras. Since pile-up was negligible, X-ray events corresponding to patterns 0–12 and 0–4 events (single and double pixels) were selected for the MOS and PN, respectively. Only good X-ray events (with FLAG = 0) were included. The low-energy cutoff was set to 300 and 200 eV for MOS and PN, respectively. The source data were extracted using a circular region centered on the source position of diameter of $50''^1$, $25''$, and $35''$ for MOS1, MOS2 and PN respectively. The diameter was smaller for MOS2 compared to MOS1 due to a dead pixel column about $26''$ from the source in the MOS2 data. ESO 113-G010 was by far the brightest X-ray source in this $30'$ EPIC field-of-view. Background data were taken from box regions on the same CCD as the source (excluding X-ray point sources). The XSPEC v11.3 software package was used for spectral analysis of the background-subtracted spectrum using the response matrices and ancillary files derived from the SAS tasks RMFGEN and ARFGEN.

3. Timing analysis

PN light curves (time bin of 500 s, and error bars of 1σ) clearly show fairly rapid variability with relatively large amplitude, both in the soft (S: 0.2–2 keV) and hard (H: 2–10 keV) energy ranges (Fig. 1; upper and middle panels, respectively). The corresponding PN time-averaged count rate observed during May 2001 (duration of ~ 4 ks) is reported (Fig. 1, dashed lines) and shows that the source was in a higher flux state for virtually all of the 2005 observation when compared to the 2001 observation. The PN average count rates in the 0.2–12 keV energy range are 2.42 ± 0.02 cts s^{-1} and 3.71 ± 0.01 , for the 2001 and 2005 observations, respectively. The corresponding Hardness Ratio, HR ($\equiv (H-S)/(H+S)$) is also displayed (Fig. 1,

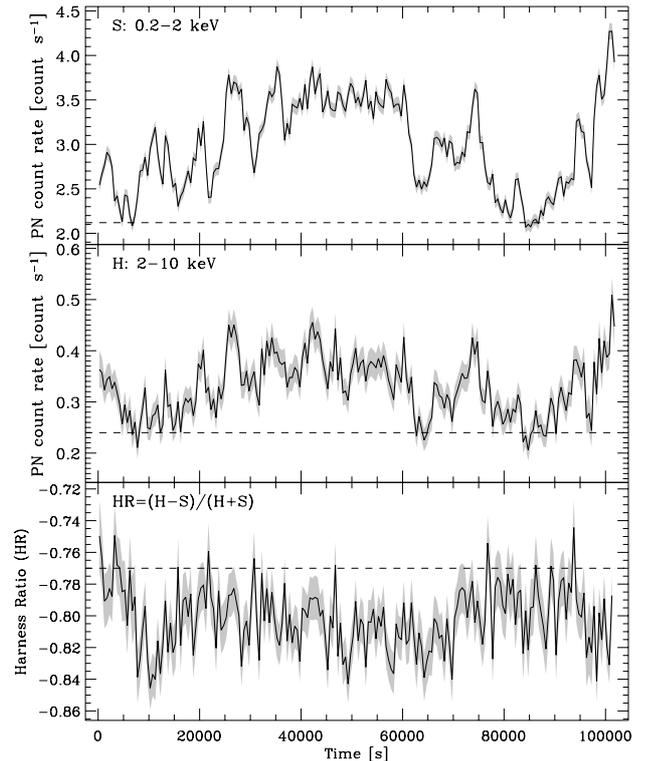

Fig. 1. Soft (S: 0.2–2 keV) and hard (H: 2–10 keV) 500-s resolution (background-subtracted) PN light curves of ESO 113-G010 (upper and middle panels, respectively), together with the hardness ratio between the two bands (lower panel). The grey stripes correspond to the 1σ error bars. For comparison the count rate and hardness ratio level found during the 4 ks May 2001 observation are reported (dashed lines).

lower panel). The error bars for the hardness ratio are obtained using Gaussian error propagation (see e.g., Pietsch et al. 2005). The 2005 HR values show that the source was on average in a softer state compared to May 2001. There was no very strong variation amplitude of the HR, except within the first 10 ks (with $\langle \Delta HR \rangle \sim 0.07$).

To quantify this variability better, we carried out timing analysis using the power spectral density function (PSD), the rms-spectrum, and flux-flux analysis. To maximize the signal-to-noise we combined events from all three instruments, re-scaling the background regions used for the MOS detectors to match the source/background area ratio of the PN. We used only data from times between 8 ks and 95 ks from the start of the observation, to remove the times of non-negligible background flaring for secure timing analysis, and merged the good time intervals of the different instruments in order to use only data received simultaneously from all three instruments. The combined events file was used to extract light curves in different bands to make the PSDs and rms-spectra. Although the instrument responses differ, in all cases (including rms-spectra) we normalize by the mean flux in each band, so the effect of the spectral response is taken out.

3.1. PSD analysis

We first consider the PSD for the light curve in the 0.3–10 keV energy range, which is shown in Fig. 2. The PSD represents the average of the (squared) amplitude of variations as a function of temporal frequency. The data are then fitted with a simple power law plus the flat level of variability due to Poisson noise expected given the error bars. A simple power-law plus

¹ For the spectral analysis (Sect. 4) the extraction region radius was taken to be the same for MOS1 and MOS2 (i.e. $25''$), in order to co-add both spectra.

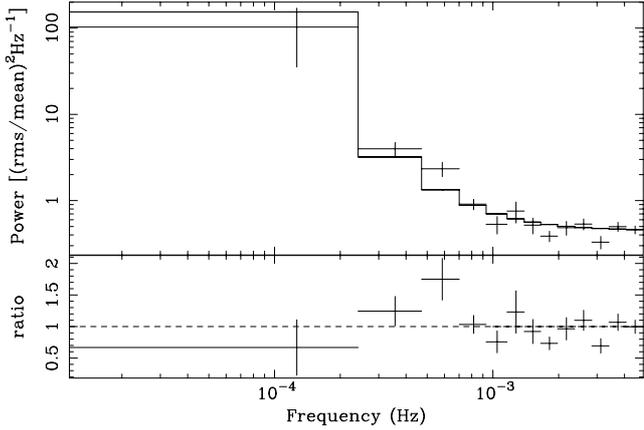

Fig. 2. 0.3–10 keV PSD of ESO 113-G010, including the ratio of the data to the best-fitting power-law plus constant noise component model (model shown as solid line).

noise is not a very good fit ($\chi^2 = 24.1$ for 11 d.o.f.), and is rejected at $>98\%$ confidence (for power-law slope $\alpha = -2.1$). Allowing the noise level to be free improves the fit to $\chi^2 = 18.9$ for 10 d.o.f., which is still rejected at $>95\%$ confidence. Finally, leaving the noise level free while allowing a break in the PSD improves the fit: fixing the low-frequency slope to -1 (similar to the low-frequency PSD shapes observed in other AGN, e.g. McHardy et al. 2005), we find a break frequency of $(5.9 \pm 1.7) \times 10^{-4}$ Hz (errors correspond to 90% confidence for a single interesting parameter), with an upper limit on high-frequency slope of $\alpha < -2.9$. The corresponding $\chi^2 = 11.9$ for 9 d.o.f., which, according to the F-test, is a significant improvement over the unbroken power-law model at the 95% level. We also find a good fit ($\chi^2 = 13.9$ for 10 d.o.f.) for an exponentially cut-off power-law, with low-frequency slope fixed to -1 and cut-off frequency $(3.7^{+1.0}_{-1.7}) \times 10^{-4}$ Hz, which we show in Fig. 3.

We caution that the possible break or cut-off in the PSD is only marginally significant, but note that, in support of these models, the product of frequency and power, which is constant on the slope $= -1$ part of the PSD is ~ 0.01 , which is of the same order as that observed in other AGN. In comparison with other AGN, the measured cut-off frequency is comparable to those measured in some other rapidly-variable Seyferts, such as MCG-6-30-15 (8×10^{-5} Hz, McHardy et al. 2005; Vaughan et al. 2003b), and NGC 4051 (8×10^{-4} Hz, McHardy et al. 2004). The correlation between AGN X-ray variability PSD break time-scale and black hole mass is now well-established. It appears that AGN PSD break time-scales can be linearly scaled down by the black hole mass to match the breaks observed in the PSDs of stellar mass black holes in X-ray binary systems (e.g. Markowitz et al. 2003; Uttley & McHardy 2005). Recently, McHardy et al. (2006) showed that the residual scatter in the mass-time-scale relation could be explained if time-scales also scale with luminosity or equivalently, accretion rate. Combining AGN and stellar mass black hole data for Cyg X-1, McHardy et al. framed the best-fitting relation for break time-scale $\log T_B = 2.1 \log M_{BH} - 0.98 \log L_{bol} - 2.33$, with T_B in units of days and M_{BH} and bolometric luminosity L_{bol} in units of $10^6 M_\odot$ and 10^{44} erg s $^{-1}$ respectively. The best-fitting PSD break time-scale we measure, 3.7×10^{-4} Hz, corresponds to $T_B = 0.03$ days. For a range in L_{bol} from $10^{44.5}$ – 10^{45} erg s $^{-1}$ (i.e. assuming a minimum equal to the sum of FIR, optical and X-ray luminosities reported by Pietsch et al. 1998, and in this work), we infer from the mass-luminosity-time-scale relation of

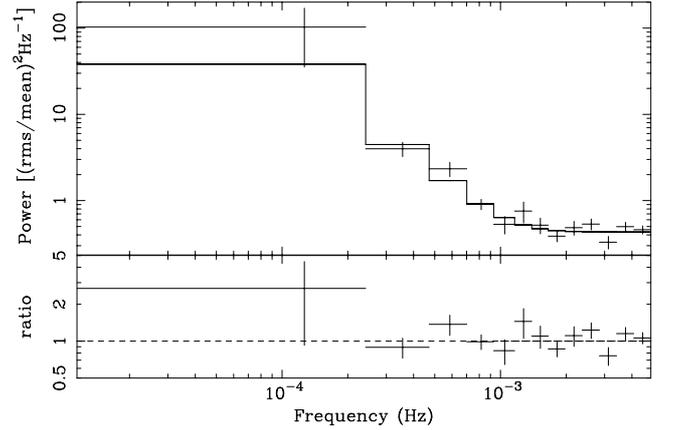

Fig. 3. 0.3–10 keV PSD of ESO 113-G010, including the ratio of the data to an exponentially cut-off power-law (with low-frequency slope $\alpha = -1$), plus constant Poisson noise component (model shown as solid line).

McHardy et al. (2006) that M_{BH} ranges from 4×10^6 – $10^7 M_\odot$ and the source is accreting at or close to the Eddington rate (assuming even higher L_{bol} implies that the AGN is a super-Eddington accretor).

We also measured PSDs using smaller subsets of the observed energy range, but due to the relatively weaker S/N of these PSDs, the energy dependence of the PSDs could not be well constrained.

3.2. The rms-spectrum

The rms-spectrum quantifies the spectral shape of the variable part of the emission (see Vaughan et al. 2003a, for a review). Specifically, one measures the root-mean-square (rms) variability in light curves made from a number of narrow energy bands or “channels”, and then normalizes each rms value by the mean in that channel to obtain the fractional rms (also known as F_{var}). A plot of F_{var} versus energy yields the shape of the variable part of the spectrum relative to the mean spectrum (i.e. independent of instrumental spectral response). The error bars are determined using the formula of Vaughan et al. (2003a). We show the measured rms-spectra in Fig. 4, obtained using light curves binned to 5 ks (top panel) and 500 s (bottom panel). The rms-spectra obtained with 500 s binning naturally includes faster fluctuations than for the 5 ks binned data, and the F_{var} measurements are accordingly larger. F_{var} appears to decrease above about 2 keV for both bin timescales. Therefore the soft X-ray excess down to 0.3 keV appears more variable compared to the hard energy range. This is different from the typical rms-spectra consistent with a broad peak in the variability amplitude between 0.8 and 2 keV, and a much lower variability amplitude below 0.8 keV (e.g., Fabian et al. 2002; Inoue & Matsumoto 2003; Ponti et al. 2006). In addition, there is a hint of a dip in the 500 s bin rms-spectrum around the Fe K α complex energy (~ 6.4 – 7 keV). This could be due to a reflected component remaining constant while the power-law continuum varies, as proposed for the two-component model (Sect. 3.3). An origin in a distant material is unlikely since no narrow 6.4 keV Fe K α line is observed (cf. Sect. 4).

3.3. Flux-flux analysis

Many AGN show a characteristic steepening of their continuum X-ray spectra at higher fluxes. A useful insight into the origin

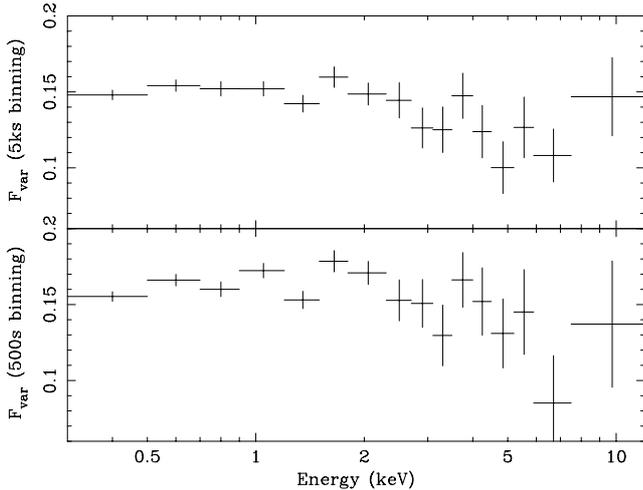

Fig. 4. The rms-spectra of ESO 113-G010, for light curve bin times of 5 ks (*top*) and 500 s (*bottom*). See text for details.

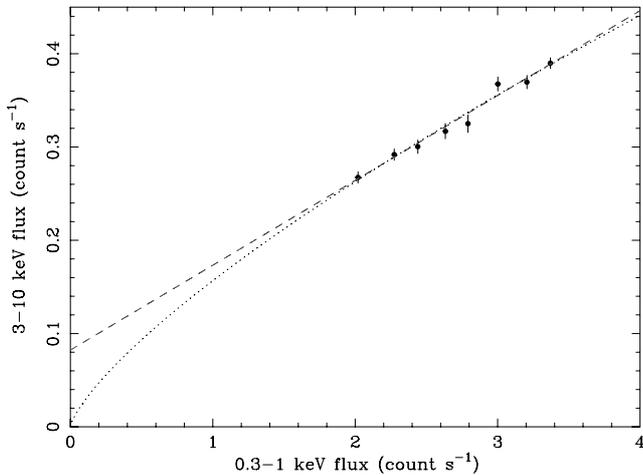

Fig. 5. 3–10 keV versus 0.3–1 keV binned flux-flux plot of ESO 113-G010, compared with a best-fitting linear plus constant model (dashed line, representing two-component spectral variation) and a simple power-law (dotted line, representing high energy spectral pivoting). The two models are indistinguishable over the relatively narrow flux range covered by the data.

of this continuum spectral variability can be obtained using flux-flux analysis. Taylor et al. (2003) showed how a simple plot of soft X-ray flux versus a harder X-ray flux can indicate whether spectral variability is due to pivoting at high energies (where the flux-flux plot takes a power-law form), or due to changes in the strength of a continuum component with a constant spectral shape plus a constant-flux, constant spectral shape harder component (where the flux-flux plot is linear with a positive intercept on the hard flux axis). Here we carry out a flux-flux analysis of the ESO 113-G010 data, using the same combined MOS and PN events data used for the rms-spectral analysis.

We first realize a flux-flux plot to compare the 0.3–1 keV and 3–10 keV ranges. We measured the fluxes in simultaneous 500 s bins, and following the approach of Taylor et al. (2003), we bin the 3–10 keV flux as a function of the 0.3–1 keV flux, obtaining the standard error in the mean 3–10 keV flux of each bin from the spread in fluxes in the bin. The resulting flux-flux plot is shown in Fig. 5. A linear plus constant model provides a good fit to the data, with $\chi^2 = 5.4$ for 6 d.o.f., for positive constant offset on the 3–10 keV flux axis of 0.082 ± 0.014 count s^{-1} (error bars are

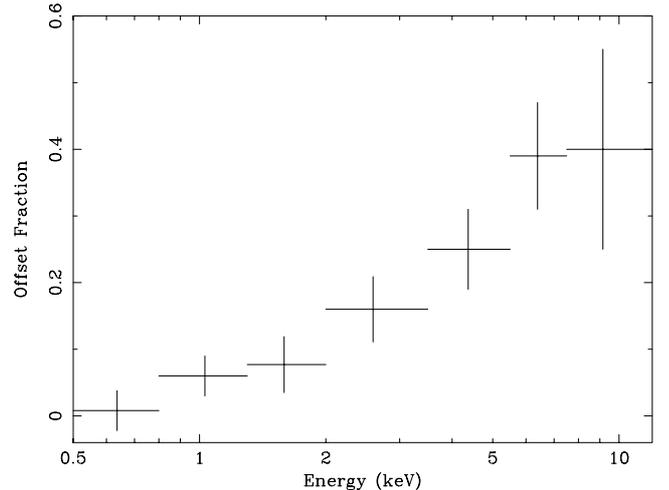

Fig. 6. Fractional offset spectrum, showing fractional constant offsets (*y*-axis intercept divided by mean flux) for a linear plus constant model fitted to various energy bands versus the 0.3–0.5 keV reference band. In the case that the two-component model for spectral variability is correct, the offset spectrum shows lower limits on the strength of the constant component spectrum relative to the mean spectrum.

1σ). A single power-law (with no offset) also provides a good fit to the flux-flux plot ($\chi^2 = 5.4$ for 7 d.o.f.), for a power-law index of 0.75 ± 0.04 . Thus, the existing data cannot distinguish between spectral pivoting of the continuum and a two-component origin for the spectral softening, primarily because the data span an insufficiently broad range of fluxes to see the characteristic change in gradient expected from the power-law.

Although we cannot distinguish between spectral pivoting and a two-component spectral model, we can use the flux-flux method to determine the shape of any constant component under the assumption that the two-component model is correct. Following the approach of Taylor et al. (2003), we fit linear plus constant models to the flux-flux plots measured from light curves obtained in a number of narrow bands. For the *x*-axis, we use the 0.3–0.5 keV band as our “reference” band. Thus all offsets measured in other bands are relative to this band only, under the assumption that there is zero flux in the constant component in the reference band. If there is a non-negligible flux in the reference band, the implied offsets in other bands increase accordingly. Thus, if the two-component model is correct the offsets we measure from flux-flux plots here represent a lower-limit on the strength of any constant component. To remove the effects of the instrument spectral response, we normalize each measured offset by the mean flux in each band. The resulting spectrum of fractional offsets is shown in Fig. 6. Since fractional offset increases significantly toward higher energies, the offset spectrum is harder than the mean spectrum, implying that any constant component is also significantly harder than the variable component, as expected if we are witnessing a constant reflection component. Notably the reflected flux contributes about 40% of the mean at the hardest energies, similar to what is observed in MCG–6-30-15 using the same approach (Vaughan & Fabian 2004).

4. Spectral analysis

In this section, we present the spectral analysis of ESO 113-G010. In this article, we focus on the analysis of the 2–12 keV hard X-ray range (not affected by WA signatures), including the

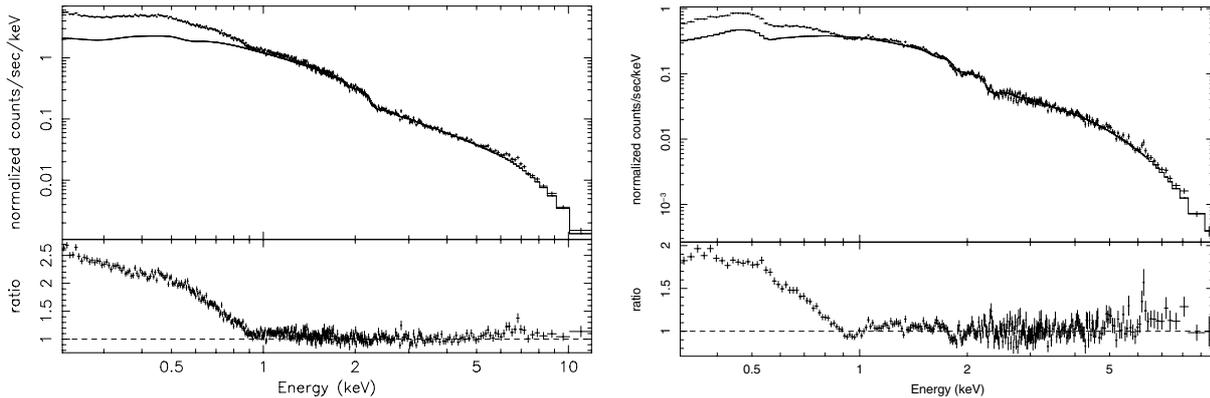

Fig. 7. Spectra of ESO113-G010 (in the observer frame) observed in November 2005. A power-law has been fitted to the 2–5 keV data and extrapolated to lower and higher energies. A significant soft X-ray positive residual is seen below 1 keV, as well as the presence of a Fe $K\alpha$ complex near 6–7 keV. For presentation, the data have been re-binned into groups of 15 bins for PN (10 for MOS), after group of a minimum of 100 and 50 counts per bin were used for the fit for the PN and MOS respectively. *Left panel:* 0.2–12 keV PN spectrum. *Right panel:* co-added MOS 0.3–10 keV spectrum.

study of both the continuum and the Fe $K\alpha$ line complex between 6.4–7 keV. We co-added the MOS1 and MOS2 data into a single spectral file to maximize the signal-to-noise ratio. The time-averaged PN and MOS spectra are binned to give a minimum of 100 and 50 counts per bin, respectively; while the sub-spectra used in the time-resolved spectral analysis (see below) are binned to give a minimum of 20 counts per bin. In all subsequent fits (above 2 keV), we include the Galactic column density ($N_{\text{H}}^{\text{Gal}} = 2.74 \times 10^{20} \text{ cm}^{-2}$), obtained from the COLDFENS program using the compilations of Dickey & Lockman (1990). Note that all fit parameters are given in the source’s rest frame, with values of $H_0 = 75 \text{ km s}^{-1} \text{ Mpc}^{-1}$, and $q_0 = 0.5$ assumed throughout. The errors quoted correspond to 90% confidence ranges for one interesting parameter ($\Delta\chi^2 = 2.71$). Abundances are those of Anders & Grevesse (1989). In the following, we use the updated cross-sections for X-ray absorption by the interstellar medium (TBABS in XSPEC) from Wilms et al. (2000).

4.1. The main spectral components

As a first step, we fit an absorbed power-law model over the 2–5 keV energy range where the spectrum should be relatively unaffected by the presence of a broad soft excess, a warm absorber-emitter medium, an Fe $K\alpha$ emission line, and a contribution above 8 keV from a high energy Compton reflection hump. In this energy range, the PN data are well fitted by a single power-law model with $\Gamma = 2.02 \pm 0.04$ ($\chi^2/\text{d.o.f.} = 228.3/214$). For comparison the value from the 2001 observation is 1.96 ± 0.22 . This power-law index is consistent with values found for broad-line radio-quiet quasars: $\Gamma = 1.90$ with a standard deviation of 0.27 (Porquet et al. 2004a). The 2–10 keV time-averaged luminosity (inferred from the parameter fit reported in Table 1) is $4.0 \times 10^{42} \text{ erg s}^{-1}$. Figure 7 displays the 2–5 keV PN spectrum extrapolated over the 0.2–12 keV broad band energy. A strong positive residual is seen below 1 keV due to the presence of a soft X-ray excess; and in addition, there is a positive residual in the 6–7 keV energy range (see Sect. 4.2). For comparison, we also report the co-added MOS1 and MOS2 spectrum, which confirms the presence of a complex soft excess as well as a positive deviation near the 6–7 keV. We henceforth focus only on the PN data, since the PN CCD has a better sensitivity over a broader energy range (0.2–12 keV) compared to the MOS CCD. However we have checked that all the spectral fits are

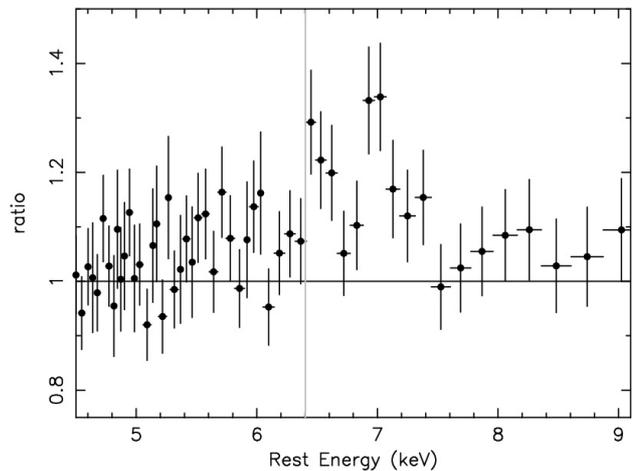

Fig. 8. Fe K line profile (quasar frame) when PN time-averaged data are fit with a power-law continuum. For presentation, the data have been re-binned into groups of 10 bins for PN, after group of a minimum of 100 counts per bin were used for the fit. The grey vertical line corresponds to 6.4 keV.

consistent with those obtained with the MOS, albeit with much lower photon statistics. We would like to note that the RGS data show the presence of several narrow blue-shifted absorption lines that reveals the presence of a warm absorber (WA) in outflow. The presence of this medium has to be taken into account in order to fit properly the overall 0.2–12 keV PN spectrum. Spectral analysis combining RGS and PN data will be presented in a forthcoming paper.

4.2. The Fe $K\alpha$ line complex

4.2.1. Time-averaged analysis

The positive residuals between 6.5–7 keV in the quasar frame can be most probably associated with a Fe $K\alpha$ complex as observed in most AGN (Porquet et al. 2004a; Piconcelli et al. 2005; Jiménez-Bailón et al. 2005). The mean iron line profile as a ratio of the continuum above 2 keV is displayed in Fig. 8, and shows a double-peaked line profile. Therefore, we fit the 2–12 keV energy range with an absorbed power-law continuum and two narrow Gaussian line profiles (Table 1). We found a much

Table 1. Best-fitting spectral parameters of PN time-averaged spectrum in the 2–12 keV energy range with an absorbed (Galactic, $N_{\text{H}} = 2.74 \times 10^{20} \text{ cm}^{-2}$) power-law (PL) component plus a line profile: ZGAUSS: Gaussian profile; and DISKLINE: profile line emitted by a relativistic accretion disc for a non-rotating black hole (Fabian et al. 1989) assuming an emissivity law q equal to -2 . (a): $R_{\text{out}} = 1000 R_{\text{g}}$. (b): $R_{\text{out}} = 1.2 \times R_{\text{in}}$. The line fluxes are expressed in units of $10^{-6} \text{ ph cm}^{-2} \text{ s}^{-1}$. F-test probabilities are calculated with the corresponding power-law model as reference. Fixed parameters are indicated by (f).

Model	Γ	Line parameters						$\chi^2/\text{d.o.f.}$	F-test
		E (keV)	σ (eV)	R_{in} (R_{g})	θ (deg)	Flux	EW (eV)		
PL	1.95 ± 0.02	–	–	–	–	–	–	327.9/294	–
PL + 2 \times zgauss	1.97 ± 0.02	$6.50_{-0.05}^{+0.06}$ 7.00 ± 0.04	10 (f) 10 (f)	– –	– –	1.6 ± 0.7 2.0 ± 0.7	52 ± 23 73 ± 26	294.7/290	>99.99%
PL + DISKLINE ^(a)	2.00 ± 0.02	6.75 ± 0.08	–	6 (f)	≥ 50	$7.7_{-2.6}^{+2.3}$	305_{-104}^{+90}	299.3/291	>99.99%
PL + ANNULUS ^(b)	1.97 ± 0.02	6.79 ± 0.05	–	191_{-63}^{+71}	45 (f)	$7.7_{-2.6}^{+2.3}$	159_{-49}^{+50}	299.1/291	>99.99%

better fit, with $\Delta\chi^2 = 33.2$ for 4 additional parameters (F-test > 99.9%). The line energies are $6.50_{-0.05}^{+0.06}$ keV and 7.00 ± 0.04 keV. The F-test probabilities for each line are 99.7% and 99.98% for the 6.50 keV and 7.0 keV lines, respectively. Allowing the line widths to vary does not significantly increase the goodness of fit, with $\Delta\chi^2 = 0.5$ for two additional parameters.

The former energy is compatible within the error bars with a line emitted by moderately ionized iron ($\sim\text{Fe XIX–Fe XXII}$). However this line is more likely a blue or red peak of a relativistic line, indeed a genuine Fe XIX–Fe XXII (L-ions) emission line complex would suffer from resonant Auger destruction (Ross et al. 1996; Liedahl 2005). The latter line energy corresponds to highly ionized iron line (Fe XXVI) or to a highly blue-shifted iron line from lower ionization matter. However there is no evidence for narrow emission from neutral iron, the 90% confidence upper-limit to a narrow ($\sigma = 10$ eV) iron line at 6.4 keV (a 6.5 keV narrow line with a width of 10 eV is also fitted to take into account its emission contribution) is only 32 eV. If the 6.5 keV line contribution is not taken into account, we would infer $EW(6.4 \text{ keV}) \leq 47$ eV. From the branching ratio of Fe $K\beta/\text{Fe } K\alpha$, expected to be less than 0.145 (Palmeri et al. 2003, and references therein), the maximum contribution of the Fe $K\beta$ (from cold iron) to the 7.00 keV line is only up to 5 eV.

We also tested if these two features can be explained by a double-peaked relativistic line profile emitted by a relativistic accretion disc for a non-rotating black hole (DISKLINE; Fabian et al. 1989). The improvement of the fit is also significant (F-test > 99.9%) and the line energy is about 6.8 keV, i.e., corresponding to a highly ionized iron ion (Fe XXV–Fe XXVI). Then, we checked whether the double-peaked like profile can be explained by emission from a disc annulus (using the DISKLINE profile with the width fixed to 20% of R_{in} , i.e. $R_{\text{out}} = 1.2 \times R_{\text{in}}$). We fixed the disc inclination to 45° (representative of an intermediate type Seyfert). We found a very good fit to the data with a line energy of 6.79 ± 0.05 keV and an inner annulus radius of $191_{-93}^{+71} R_{\text{g}}$, indicating that the line is not emitted in the inner part of the disc. In the case where the disc inclination is not fixed to 45 degrees, then the line solution is degenerate, whereby the inner annulus radius increases with the disc inclination, while the line energy decreases.

Monte Carlo simulations were done to assess the significance of detecting the emission complex in this time-averaged spectrum. These simulations, described in detail in the Appendix, demonstrate that regardless of the model used, the emission complex is indeed significantly detected.

We also checked for an upper limit to a line at 5.39 keV, since such a line was found in the 2001 XMM-Newton observation of

May 2001. We fixed the energy of the line to 5.39 keV (see below), and the line width to 0.1 keV (as done in Porquet et al. 2004b). We find $EW \leq 22$ eV (at 90% confidence level for one interesting parameter).

For comparison, we have re-processed the XMM-Newton May 2001 observation with the same version of the SAS (SAS 6.5.0) used for the 2005 observation. We fit the data with an absorbed (Galactic column density) power-law in the 2–10 keV energy range and four Gaussian lines in order to take into account the emission contribution of the lines near/at 5.4 keV, 6.4 keV, 6.5 keV, and 7.0 keV. The three latter line energies are fixed as well as their widths to 10 eV. Only the energy of the first Gaussian line is left free to vary with the width fixed to 0.1 keV (as done in Porquet et al. 2004b). One should notice that in Porquet et al. (2004b), only the line at 5.4 keV was fitted. We found for the four lines: $EW_1 = 246 \pm 147$ eV ($E_1 = 5.39 \pm 0.09$ keV), $EW_2 \leq 190$ eV ($E_2 = 6.4$ keV), $EW_3 \leq 100$ eV ($E_2 = 6.5$ keV), and $EW_4 \leq 208$ eV ($E_2 = 7.0$ keV). The EW for the line at 6.4 keV, 6.5 keV, and 7.0 keV are compatible with the values found during the 2005 observation. For the line at ~ 5.39 keV, the EW are not compatible and would mean that if the line detected during the 2001 observation is real, it is transient.

4.2.2. Time-resolved analysis

To test for possible rapid shifts in the energy and/or flux of the Fe $K\alpha$ emission complex, we have created X-ray intensity maps in the energy-time plane using the PN data. Photons from the source cell were accumulated in pixels in the energy-time plane. The pixel distribution was smoothed in energy by the instrumental resolution, using a Gaussian of 140 eV (appropriate for the single plus double events with the latest calibration), and smoothed in time using a top-hat function of width 20 ks. Each time-slice was background-corrected by subtracting a time-dependent background spectrum measured in an off-source region on the same detector chip as the source. The source continuum was modeled as an absorbed power-law, of variable amplitude and slope but time-invariant absorption column density. This continuum was subtracted, leaving positive and negative residuals that comprise noise plus any emission or absorption components on top of the continuum. More information about this method is given in Turner et al. (2006). The “signal-to-noise” (S/N) map presented in Fig. 9 is the ratio of the fluctuation amplitude to the calculated noise.

The highest S/N observed is 4 and there are several points of significant excess emission above the continuum. However, we note here that the energy-time map highlights fluctuations above

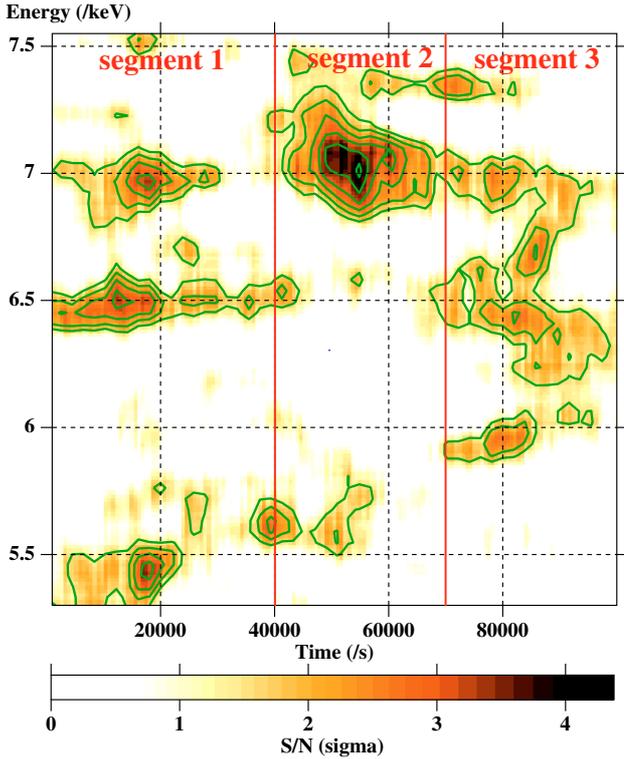

Fig. 9. Energy-time map. The energy values are in the quasar frame. The contours represent 1.5–4.0 sigma above the continuum (in 0.5 increments), with darker bins representing an excess above the continuum. The segments 1–3 (delimited by red vertical lines) correspond to the time selections used for the time-resolved spectroscopic analysis. See text for explanation.

the continuum which may be real spectral features, but does not assess the significance of variations in those features, assuming they are real. The apparent fluctuations in the energy-time map could be consistent with the complex emission features detected in the time-averaged spectrum being *constant*, e.g. if the average significance in one independent 10 ks segment is 2 sigma above the continuum, then we might expect statistical variations from 0–4 sigma in a 100 ks observation.

To quantify whether the line features are variable, we split the data set into three time intervals, 0–40 ks, 40–70 ks and 70–100 ks, which are chosen to maximize the differences in the Fe K line region which are highlighted by the energy-time map. Note that in the case that the lines are constant, this approach essentially maximizes the effect of noise fluctuations that are picked up by the energy-time map, so that the statistical tests we carry out are in some sense the most optimistic for detecting line variability. The line profiles for each segment (data/model ratio for a power-law continuum over the 2–10 keV energy range) are shown in Fig. 10. We then fit these three sub-spectra with (individual or double) Gaussian line profiles; the results are reported in Table 2. Though the line profiles in Fig. 10 appear to be different, adding a double Gaussian line profiles at 6.5 keV and 7.0 keV (as found in the time-average spectrum) are significant (F-test significance = 99.5–99.97%) in all segments. We also carried out Monte Carlo simulations to verify the significance of lines fitted to the individual sub-spectra; we detail these results in the Appendix (see A.3), but note here that they confirm that the lines are significantly detected in the individual sub-spectra.

Having verified the statistical significance of the lines in each of the 3 segments, we check for significant variability of the line

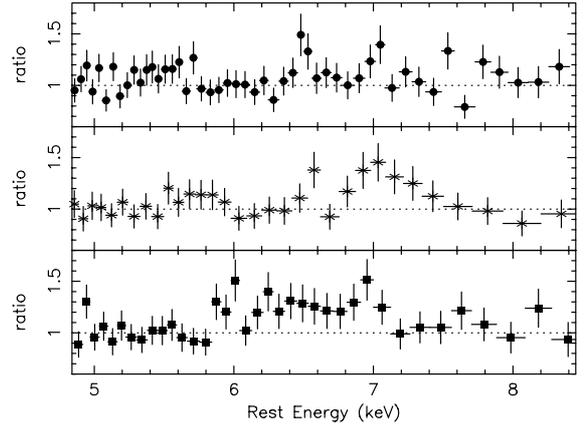

Fig. 10. The PN data/model sub-spectra of ESO 113-G010 (quasar frame) for the three time intervals. The data have been fitted assuming a power-law underlying continuum. *Upper panel:* 0–40 ks sub-spectrum (segment 1). *Middle panel:* 40–70 ks sub-spectrum (segment 2). *Lower panel:* 70–100 ks sub-spectrum (segment 3).

flux. First, we fit simultaneously all segments with a power-law model plus two Gaussian lines with line energies fixed to 6.5 keV and 7.0 keV and line widths and line normalisations are free to vary within each segment. The contour plots at 90% confidence level for two interesting parameters ($\Delta\chi^2 = 4.61$) are reported for each line in Fig. 11, and show that assuming two Gaussian lines there are no statistically significant line variations. We also simulated 100 spectra using the FAKEIT command, and assuming an initial model consisting of a power-law plus a single Gaussian emission line at either 6.5 or 7.0 keV. We assumed that the line is intrinsically constant, with parameters described by values, and used an exposure time of 29.8 ks. We found that the observed values of line intensity and line width σ were usually consistent with the resulting spread in 100 simulated values. This suggested that we could not rule out at high significance the hypothesis that these parameters are intrinsically constant.

5. Discussion

We report the data analysis results of a long 100 ks XMM-Newton observation in November 2005. We have used both model-independent techniques (e.g., rms-spectra, flux-flux plots) and spectral analysis (time-averaged and time-resolved spectroscopy).

5.1. Timing analysis

Light curves reveal that this source was highly variable on short timescales (~ 500 s), and was on average in a higher/softer state compared to the May 2001 observation. The Power Spectral Density (PSD) analysis indicates (at 95% confidence) a break at a frequency of $3.7^{+1.0}_{-1.7} \times 10^{-4}$ Hz. This measured cut-off frequency is comparable to those measured in some other rapidly-variable Seyferts, such as MCG–6-30-15 and NGC 4051. For a range in L_{bol} from $10^{44.5}$ – 10^{45} erg s $^{-1}$ (i.e. assuming a minimum equal to the sum of FIR, optical, and X-rays luminosities, reported by Pietsch et al. 1998, and in this work), we infer from the mass-luminosity-time-scale relation of McHardy et al. (2006) that M_{BH} ranges from 4×10^6 – $10^7 M_{\odot}$ and the source is accreting at or close to the Eddington rate (assuming even higher L_{bol} implies that the AGN is a super-Eddington accretor).

Table 2. Best-fitting spectral parameters of PN time-resolved spectra in the 2–10 keV energy range with an absorbed (Galactic, $N_{\text{H}} = 2.74 \times 10^{20} \text{ cm}^{-2}$) power-law (PL) component plus a Gaussian profile (ZGAUSS): The line fluxes are expressed in $10^{-6} \text{ ph cm}^{-2} \text{ s}^{-1}$. F-test probabilities are calculated with the corresponding power-law model as reference. (*) The F-test probability for freeing the line width in the fit is 92%. (a) Monte-Carlo simulations have been performed (see text). Fixed parameters are indicated by (f). Parameters are indicated by (f).

For segment 2, only an upper limit is found, corresponding to the continuous line. *Right panel:* line at 7.0 keV. For segments 1 and 3, only an upper limit is found.

The rms-spectra obtained using light curves binned to 5 ks and 500 s show that F_{var} appears to decrease above about 2 keV for both bin timescales. Therefore the soft X-ray excess down to 0.3 keV appears more variable compared to the hard energy range. This is different from the typical rms-spectra from other Seyferts, which tend to show a broad peak in the variability amplitude between 0.8 and 2 keV, and a much lower variability amplitude below 0.8 keV (e.g., Fabian et al. 2002; Inoue & Matsumoto 2003; Ponti et al. 2006). From the flux-flux analysis,

the existing data cannot distinguish between spectral pivoting of the continuum and a two-component origin for the spectral softening, primarily because the data do not span a broad enough flux range to see the characteristic change in gradient expected from the power-law. However, in the case of the two-component model being correct for this source, the fractional offsets measured in the flux-flux plots increase significantly toward higher energies (similarly to what is observed in MCG–6-30-15), as expected if we are witnessing a constant reflection component.

Because there is no evidence for distant, cold material such as a torus (Sect. 4), then if the Compton reflection component is real, the reflection is more likely associated with the accretion disc.

5.2. Spectral analysis: the FeK α line complex

Instead of a single highly redshifted line at about 5.4 keV as observed in the 4 ks May 2001 observation, we found in the November 2005 time-averaged observation two narrow Fe K α emission lines at about 6.5 keV and 7.0 keV. The former rest-frame energy is compatible within the error bars with a line emitted by moderately ionized iron (\sim Fe XIX–Fe XXII). However this line is more likely a blue or red peak of a relativistic line, indeed a genuine Fe XIX–Fe XXII (L-ions) emission line complex would suffer from resonant Auger destruction (Ross et al. 1996; Liedahl 2005). The latter line energy corresponds to highly ionized iron line (Fe XXVI) or to a highly blue-shifted iron line from lower ionization matter. The two features can be well represented by a double-peaked line profile from the disk with a rest-frame energy of 6.75–6.80 keV. In case of an annulus DISKLINE profile an inner radius of about 200 R_g is inferred. Alternatively the Fe XXVI line could be the signature of a strongly photoionized ($\log \xi > 3$), circumnuclear matter (seen in emission) with an iron overabundance of a factor 3, and/or very high column densities with $N_{H,warm} \gg 10^{23} \text{ cm}^{-2}$ (Bianchi & Matt 2002). There is no significant evidence for line variability, however with the current data we also cannot reject the possibility that the lines do vary in response to continuum variations. Further XMM-Newton monitoring of this source can help to establish or reject line variability at different time-scales (from day(s) to months) and also allow us to determine if the line profile is indeed double-peaked and originates in the disk or if there exist independent or transient red/blue-shifted emission lines. Shorter time-scales will only be reached by higher collecting area (and resolution at the iron K α energy band) instruments such as *Constellation-X* and *XEUS*.

In the May 2001 observation of ESO 113-G010 we observed a line feature at 5.39 keV, which was detected at 99% confidence (based on Monte Carlo simulations) with $EW = 233 \pm 140 \text{ eV}$. We notice that a weak feature is seen at 5.4 keV near 20 ks in the energy-time map (Fig. 9), but this line has a detection probability of only 38% using Monte-Carlo simulations. The 90% upper limit on EW for a 5.39 keV line in the total observation is 22 eV (Sect. 4.2.1). Therefore, if the line observed in May 2001 is real, it is transient. We note however that, if we treat the total data set on ESO 113-G010 as a set of independent ~ 4 ks segments, the chance of seeing a 99% fluctuation in a single segment by chance becomes quite high. However, in support of the possibility the 5.39 keV feature was real, we also point out that the flux and spectral hardness in May 2001 corresponds to the extreme low and high values observed in 2005 (see Fig. 1), which might be more favourable to transient line formation (though we also note that such a line feature was not observed during the 2005 flux minimum).

In addition, as suggested by the 2001 observation, no significant constant narrow 6.4 keV Fe K α line is observed with an upper-limit of $< 32 \text{ eV}$, hence excluding any dominant emission from distant cold matter such as a torus. For a neutral solar abundance reflector subtending $2\pi \text{ sr}^{-1}$ to the line of sight, illuminated by a $\Gamma = 1.9$ continuum and inclined at 45° , the expected iron line equivalent width is $\sim 125 \text{ eV}$ with respect to the primary continuum (George & Fabian 1991). Thus in ESO 113-G010 any cold, Compton-thick reprocessor outside of the line of sight

is likely to subtend a much smaller solid angle, of the order $< \pi/2 \text{ sr}^{-1}$.

The optical classification as a Seyfert type 1.8 of ESO 113-G010 (observed in November 1996; Pietsch et al. 1998) suggests the presence of a reddened broad line region (BLR). For a reddening of $E(B - V) = 0.8\text{--}1.0$, typical for a Seyfert 1.8 (Véron-Cetty & Véron 2006), the hydrogen column density would be equal to or greater than about $4\text{--}6 \times 10^{21} \text{ cm}^{-2}$ (assuming a dust-to-gas ratio equal to or smaller than the Galactic value; Bohlin et al. 1978). However, during the present 2005 XMM-Newton observation (also suggested by the 2001 observation), instead of an intrinsic neutral absorption (in addition to the Galactic column density value of $2.74 \times 10^{20} \text{ cm}^{-2}$) expected about below 1 keV, a soft excess is observed. A resolution of this apparent discrepancy, without the need to invoke a very high dust-to-gas ratio is either that dust that obscures the BLR clouds could lie out of the direct line of sight toward the X-ray emitter; or dust responsible for the BLR reddening could be mixed in with the warm absorber-emitter medium detected in the RGS spectrum. Alternatively, the apparent disagreement between the (non-simultaneous) optical and X-ray classifications could be explained by a time variability of the optical and/or X-ray absorbing properties (e.g., H1320+551: Barcons et al. 2003).

Appendix A: Monte-Carlo simulations

A.1. Method

We carried out rigorous tests of the significance of the lines in the time-averaged spectrum and in each segment using Monte Carlo simulations; see Porquet et al. (2004b) and Markowitz et al. (2006) for full details. For the null hypothesis, we assumed that the spectrum is simply an absorbed power-law continuum, with the same parameters as the absorbed power-law model fitted to the real data in each segment. We used the XSPEC FAKEIT command to create 1000 fake EPIC-pn spectra corresponding to this model, with photon statistics appropriate for each exposure (38.6, 24.0, and 26.9 ks for segments 1–3, respectively), and grouped each spectrum to a maximum of 20 counts per bin. For each faked spectrum, we re-fit the null hypothesis model, yielding a “modified” null hypothesis model. We ran FAKEIT a second time using this re-fit model, again with the appropriate exposure time; this process accounts for the uncertainty in the null hypothesis model itself. For each new spectrum, we re-fit the null hypothesis model, recorded an initial χ^2 value, and then added a Gaussian component to the fit, as described below. The line centroid energy was constrained to the 4.5–8.0 keV range, and the line normalization was allowed to be positive or negative. We stepped the Gaussian centroid energy over this range in increments of 0.1 keV, fitting separately each time to ensure the lowest χ^2 value was found. For each spectrum, we compared the lowest χ^2 value with that from the null hypothesis fit, to obtain 1000 simulated values of the $\Delta\chi^2$, which we used to construct a cumulative frequency distribution of the $\Delta\chi^2$ expected for a blind line search in the 4.5–8.0 keV range, assuming the null hypothesis of a simple power-law with no line is correct.

A.2. Results for the time-averaged spectrum

The observed 6.5 and 7.0 keV lines had $\Delta\chi^2$ values of 13.2 and 19.0, significant at 97.4% and 99.7% confidence, respectively, according to the simulations. However, since we have detected two lines that are close in energy, we can quantify their detection significance as a pair. The likelihood that both lines are due to photon noise is $(1-0.974)(1-0.997) = 8 \times 10^{-5}$, i.e., the pair is significant at just over 99.99% confidence. As an alternative quantification of the detection significance of the pair, we ran simulations which tested for the presence of a pair of narrow Gaussians with a fixed energy separation of 0.50 keV and with both line intensities left free. The observed $\Delta\chi^2$ value of 33.2 is significant at >99.9% confidence. However, as there was no a priori expectation for the value of the energy separation, using such a line profile tests only a small subset of the full range of line pair profiles possible, and so this probability should be treated as an upper limit. Assuming the annulus profile is correct, the observed $\Delta\chi^2$ value of 28.8 corresponds to a detection probability of >99.9%.

A.3. Results for the time-resolved sub-spectra

Segment 1 (0–40 ks): The observed 6.51 keV line had a $\Delta\chi^2$ of 9.4, significant at 85.8% according to the Monte Carlo simulations. The observed 7.03 keV line has a $\Delta\chi^2$ of 4.2, significant at only 18.6% confidence, i.e., we cannot significantly rule out the hypothesis that the 7.03 keV feature is due to photon noise. However, the likelihood that *both* lines are due to photon noise, calculated in the same manner as for the time-averaged spectrum, is 0.116, i.e., the pair of lines is significant at 89.4%. Performing Monte Carlo simulations assuming two lines with a fixed energy separation yields (an upper limit of) 92.0% confidence.

Segment 2 (40–70 ks): The simulations suggest the broad Gaussian 7.0 keV line, with an observed $\Delta\chi^2$ of 17.9, is significant at 99.7% confidence.

Segment 3 (70–100 ks): The simulations suggest the broad Gaussian 6.7 keV line, with an observed $\Delta\chi^2$ of 13.9, for only 3 additional parameters is significant at 99.9% confidence.
